the practical utility of measures of segregation and disinfection. Tuberculosis was a disease that stood by itself and was a law unto itself, it mocked at the measures that succeeded in the other infectious diseases. Infection might not exist, or might be suspended for years, and cause "like a thief in the night." Accordingly compulsory notification was a mere fetish of officialism, costly, irritating to patient and doctor alike, and futile—because such notification could lead to no constant, immediate, rapid, or lasting success. Compulsory notification had a semblance of justification only when the sufferer expelled in the act of coughing droplets or masses of sputum which might be conveyed directly or indirectly to those in the immediate neighbourhood. It could not either quench the infection at its source, or prevent or heal a chronic disease already existing which was quite beyond the reach of measures of segregation and disinfection. The true solution of the tuberculosis problem would be found rather in the treatment of tuberculosis in the early stages by scientific measures which would largely prevent chronic tuberculosis passing on to those stages when the disease became infectious. The treatment of early non-infectious tuberculosis was the key to the prevention of infectious phthisis. Hitherto in tuberculosis medical thought had been devoted too much to ideas of prevention and too little to methods of treatment. If the physician, by treatment, could prevent early non-infectious tuberculosis becoming infectious phthisis or consumption—and Dr. Wilkinson honestly believed he often could—he saved the family from the risks of infection. The infectious form would sometimes develop, and then suitable measures must be adopted. But the physician must continue to treat, because by a proper course of tuberculin treatment it was almost the rule that cough and expectoration ceased, and thus the victims ceased to be a danger to their friends and relations. When the disease became infectious public health authorities must take a hand by providing free examinations of suspected material by properly constituted experts at public institutions. In this way the open or infectious forms of pulmonary or renal tuberculosis would be notified automatically to the public health department, which should do all in its power to help and support the family physician or general practitioner in seeing that measures were taken to prevent constant and repeated infection of the younger members of the family. That was all the notification that was required until the family doctor realized that the victim of infectious phthisis was too ill or too weak to conform to simple rules of cleanliness and decency, when the victim of poverty should be provided with home and shelter where the risk of infection could be rendered negligible. Sanatoriums if devoted to this beneficent work, would quadruple their usefulness. Institutions for the reception of advanced cases of consumption were next in importance to measures for the early diagnosis and treatment of non-infectious and infectious forms of tuberculosis by general practitioners. In tuberculous meningitis, tuberculosis of bones and joints, pleurisy or chronic tuberculous peritonitis, the infective agents were securely imprisoned in the tissues and could not escape or infect the healthy. Even lupus, which was essentially a disease of early life in certain climates and conditions, was only a danger in the family circle where it occurred and then only to the children. Tuberculosis in childhood and even in adult life, existed mainly in the system of lymphatic vessels and glands and tubercle bacilli might circulate in the blood for years before chronic apical tuberculosis began and chronic apical tuberculosis might exist for years before the disease became infectious. The policy of ignoring pulmonary tuberculosis till tubercle bacilli were found in the sputum was both unfair to the victim of the disease and dangerous to the family. Many a doctor who acquiesced in this policy came to think that he need not bother till tubercle bacilli had appeared yet as soon as tubercle bacilli were found he must tell the world that there was infectious disease and at the same time try to persuade some official—either the tuberculosis officer or a medical officer of a hospital for consumption—to favour his patient with prolonged treatment in a sanatorium to the exclusion of nine or ten others equally deserving. There were better ways of treating tuberculosis than the

methods of the sanatorium. The collective opinion of general practitioners would indicate probably that sanatoriums had failed to help those who most needed help—the industrial classes of our great cities. German doctors had done their best to advertise sanatorium methods, but the statistics of Engelmann, Wecker, and Hamel did not justify the policy of sanatorium treatment for the poor as a simple, comprehensive, economical, and effective means of solving the problem of treatment. Outside Germany, Great Britain alone had blindly followed the lead of Germany, the home of bureaucracies. In spite of Germany's lead there was nothing in science or practice to justify the existence of a bureaucracy to deal with the problem of tuberculosis. The scientific methods of Koch furnished the secret key to the early diagnosis and successful treatment of tuberculosis, and early diagnosis and successful treatment were the *métier* of the physician. The indispensable and invaluable auxiliary of the family doctor in the homes of the poor was the district nurse, not the health visitor. Automatically district nurses should be sent to advise and direct the mother how to prevent infection among her children as soon as a case of infectious tuberculosis had been reported to headquarters by the official bacteriologist. Thus an automatic chain connected the infectious victim with the official bacteriologist, who automatically reported to headquarters, and headquarters supplied the district nurse to work in the homes of the poor under the doctor.

The problem for the doctor, said Dr Wilkinson, was to learn the best means of securing the highest degree or titre of immunity and maintaining it. Every plan of treatment demanded a close study of the processes, conditions, and phenomena of immunity, so that we might exploit them in the interest of the patient. The only way of treating tuberculosis was to imitate Nature and to assist the action of tissue cells in defending themselves by means of carefully graduated doses of antigenic substances. By experience we learnt how to improve and maintain an efficient mechanism of immunity and to master the principles and rules that guided us in the selection of the suitable cases for the use of tuberculin and in the plan of treatment. Tuberculin was in no sense a short cut to success. We merely supplemented the ordinary methods of examination and treatment with the weapons science had provided through the genius of Koch. None but experts should give doses of tuberculin for diagnosis or treatment, and not even the best qualified practitioner of medicine should use tuberculin in treatment unless he had had at least three months' training at a tuberculin dispensary.

The Association for the Prevention of Tuberculosis was even now engaged upon a fantastic chimera which was doomed to failure. Rather than waste money in a quixotic effort to teach ignorant people how to prevent tuberculosis when even medical men could not do it, we should design a plan, based on scientific knowledge, for the education of medical men in the difficult task of recognizing and treating this elusive disease, so as to prevent it becoming infectious. We should learn that living tubercle bacilli had been at work in the parts and organs most prone to infection for months and years before physical signs could reveal them. Even x-ray methods could not tell us whether there were living and active tubercle bacilli in the tissues. Every family physician should realize that the disease had certain peculiar and distinctive characters of its own by which it could be detected in its first beginnings. The mysterious secret of tissue energy discovered by Koch, and pronounced by him to be the sole and trustworthy means of discovering tuberculosis in the earliest stages, was called allergy. Tuberculin could reveal serious tuberculosis that could not be detected in any other way.

The borough of St Pancras, said Dr Wilkinson, contained about a quarter of a million souls. The yearly loss of life from tuberculosis would be nearer 300 than 200, if every dead body had been examined by a pathologist and there had been no war. There were besides 2,000 victims still alive, wending their way slowly down into the valley of the shadow of death. Last year, in spite of the vaunted work of the Ministry of Health for sixteen years, £3,150,000 had to be provided by the taxpayer for dealing with consumption. St Pancras's share was about £22,000

a year. The family doctors, provided they had learnt the scientific methods of diagnosis and treatment, had a claim upon most of this money. The sum of £22,000 allowed £10 for the treatment of each patient. At such a cost, by the methods of the tuberculin dispensary, five to ten times as many patients could be treated as sanatoriums could treat, with better results, and the victim of the disease could often go on doing his work and provide for his family. This system would relieve the taxpayer, and would convert weakly or disabled workers into relatively healthy, capable, and efficient producers, often without any disturbance in the labour market, without any sacrifice of work or wage, without any demoralizing doses, without any breaking up of the family unit, and with a good chance of preventing that dislocation in every sort of industrial, commercial, social, or other enterprise which was inevitable when the disease tuberculosis infiltrated, as it did, every grade of society. Sanatorium treatment was a curse to the taxpayer, to the patient, and to the sanatorium doctor. Much money was wasted on expensive buildings, and heavy expenses for doctors, upon nurses, upon travelling, upon upkeep and food. Loss of occupation was an inherent condition of sanatorium treatment. The system was grossly unfair to the majority of sufferers, and was both inadequate and disappointing for the industrial workers, who "ask for bread and are given a stone." The scientific method had not had a fair trial in any country, perhaps because it was highly technical and difficult to learn, difficult to teach, and difficult to put into practice, but chiefly because the evaluation of any method of treating tuberculosis demanded exacting conditions. For such investigation all the cases treated must be recorded, the method on trial must be as far as possible the exclusive method, the diagnosis must be beyond doubt, and all the cases must be controlled by after-examinations at least once a year for four or five years after the beginning of treatment. The reason why leading doctors and authorities had rejected Koch's work and teaching upon the value of tuberculin was that they had never seriously investigated it under these conditions. Wrong doses had been given in the wrong way, at the wrong time, in the wrong cases. Moreover, the false idea existed that large doses and highly active antigens (unchanged tuberculi), which Koch always recommended, were dangerous, and neither the Brompton Hospital physicians who investigated tuberculin, nor Wright, nor Dreyer, realized that the value of any method of treating chronic tuberculosis could not be assessed unless the observations had been controlled by after-examinations made several years after the beginning of treatment. Experiences at the Tuberculin Dispensary in London had shown that in all the patients in Stage 1 and Stage 2 in which tubercle bacilli were found in the phlegm, 68 per cent were alive at the end of eight to ten years, and 70 per cent were able to follow their ordinary avocations. The London County Council results in similar cases under sanatorium treatment were 28 per cent alive at the end of four years. The advocacy of tuberculin, both as a diagnostic and curative agent, rested upon facts that could not be impeached. One could see the healing of lesions in the eye, in the larynx and epiglottis, in the skin, on the palate, on the tongue, in the nose, in the skin, in the digits, in the bladder. Further, one could see tubercle bacilli disappear from the urine in genito-urinary tuberculosis, and at the same time pus cells and morbid elements disappear, implying healing of the genito-urinary tract. One could see tubercle bacilli disappear from the phlegm in chronic infectious phthisis, and at the same time cough lessen and phlegm diminish till it likewise disappeared. One could see sinuses leading from tuberculous foci in bone or joints or from a cascating epididymis slowly healing till a beautiful smooth parchment-like scar was all that was left of the running sore. In all these cases there was evidence of allergy, justifying confidence in tuberculin as an unerring diagnostic agent under control, and as a curative agent when all other remedies had failed.

Dr Camac Wilkinson concluded by inviting members of the St Pancras Division to examine the work carried on at the Tuberculin Dispensary.

Reviews.

RADIOGRAPHY OF THE CHEST

THE second volume of the late Dr WALKER OVEREND'S book entitled *The Radiography of the Chest*,¹ which deals with non-tuberculous affections was finished at the time of the author's death two years ago and has been seen through the press by his son, Dr T D Overend. The first volume, which dealt with pulmonary tuberculosis, was favourably reviewed in these columns in 1920.

The author deals with his subject-matter in a series of eleven chapters, each complete in itself, and each concludes with a reference to the more important papers previously published which bear on the disease under consideration. All the radiographic illustrations are together at the end of the book, this is an arrangement which cannot be commended, as in reading the text it is constantly necessary to turn to the end pages and to sort out the requisite illustrations. Taken as a whole, this book is admirably written and arranged. It has the great advantage over many radiological books and papers which deal with intrathoracic conditions inasmuch as it is the work of one who was an exceedingly well qualified physician with special knowledge of diseases of the chest and Dr Overend also had made for himself a reputation as a radiologist in the days when technique was not so easy as it is now. In the whole field of radiological work there is probably nothing more difficult than the interpretation of "chest radiographs," and every radiologist is aware of the difficulty and danger of attempting to make a correct radiological diagnosis without having a consultation with the physician in charge of the case. When the physician is himself the skilled radiologist, then his individual will, as in the present case, is such that it deserves careful consideration from both physicians and radiologists.

We do not propose to analyse critically the various chapters which deal with practically all the conditions occurring in the thorax which may give rise to x-ray abnormalities. It is sufficient to point out that while it is evident that the author had read largely and had digested his reading the bulk of the written matter is not the quotation of other people's opinions, but the result of his own work and his own opinions. The radiographic illustrations are on the whole sufficient and are reproduced very well. The letterpress is good. This is a book which should be useful to all physicians, general practitioners, radiologists and students who are making a special study of radiology.

OTO-RHINO-LARYNGOLOGY

TEN years have passed since the publication of the fourth edition of Lamb's *Practical Guide to Diseases of the Throat, Nose, and Ear*. It is with pleasure we notice a new edition.² The author, as he mentions in his preface, having retired from practice, has left the revision of the fifth edition to his friend and former pupil Dr Frederick Svedenhorn. While some eighty pages of new matter have been added, the original character of the book has not been altered. The object has been to present to the student and practitioner not a complete textbook but a "guide," enabling them to recognize the various common abnormalities and to treat minor ailments of the throat, nose, and ear. The new matter includes an important chapter of original observations on the radiography of the accessory sinuses of the nose. The chapter is illustrated with thirty-one full page plates of shadowgraphs demonstrating the indications in radiography and its value. Some of the new matter may be provocative of criticism. For the removal of tonsils and adenoids in children especially in the outpatient department, where the child cannot be admitted afterwards but must return home within a few hours,

the reviser prefers to operate without an anaesthetic of any kind. In his belief that method is better in every way. It does not matter whether the child has had food given to it just before the operation, as there is never any vomiting. Some parents will feed their children just before coming to hospital, whatever instructions they may have received beforehand. It is further remarked that without an anaesthetic of any kind "there is no danger at all during operation post-anaesthetic pneumonia is avoided, the loss of blood at the time of operation is one-third or less of the amount lost with an anaesthetic, and the child is quite ready to go home within an hour." The reviser firmly believes there is less shock. He is well aware that this method does not meet with general approval and he recommends it only to those who operate fairly frequently for this purpose and who are expert. The removal of tonsils and adenoids in children in an outpatient department where the child cannot be admitted afterwards into the hospital presents obvious difficulties, and is a matter on which sharply divergent views have been expressed in our columns recently.

VIEWS ON THE MEDICAL LIFE

IT is a very trite remark that the medical profession offers unique opportunities for the student of mankind. In this may perhaps be found the reason why so many novelists and dramatists have begun their careers in medicine, and certainly when a doctor with the literary instinct finds time to put his thoughts and reflections on paper it nearly always results in a volume which is well worth reading. Dr C O HAWTHORNE has fortunately found such time, and in a little book entitled *Short Essays on Medical Topics*³ he discourses on many varied themes. The first, on the subjective influence of the study of medicine, may perhaps be taken as his *credo*, and he analyses very soundly and sympathetically the attractions which the medical profession has to offer. Dr Hawthorne does not quarrel with the hard-worked plitudes about the nobility of the calling and the undesirability of making a money reward the first or chief consideration, but he seeks to show that, side by side with altruistic motives, the medical man's reward lies largely in the fact that in the course of his daily work "it is to the heart as well as to the head that the appeal is made, and the whole man, not merely his intellectual faculties, is encouraged to a liberal growth and a generous development." His opinions on unqualified practice, on specialism, on professional secrecy and on ophthalmic medicine, must be well known to a considerable number of our readers and they find cogent expression in sundry chapters of this volume. We have never seen the advantages of a university training to the right kind of medical student so well set out in a few words as in the essay on the universities and medicine, here is a large and balanced view concisely expressed in admirable English. This philosophical outlook and command of phrase will strike the attentive reader on many other pages. A spirited reply to the claims of Christian Science is well worth careful study for the way in which the superficial philosophy which masquerades as "science" is skillfully dissected. In this essay Dr Hawthorne is reviewing a book about the Christian Science cult by C H Lea and leaving aside the obvious criticism of the "cures" claimed by the author he attacks the philosophic conceptions of a perfect universe in which apparent imperfections are due to "false human consciousness" so that pain and disease are considered as unreal because of the untrustworthiness of our senses. The medical man Dr Hawthorne suggests has learnt from his experience neither blindly to trust nor obstinately to mistrust either his physical senses or his human consciousness. He endeavours to judge of the reliability of these processes by developing his common sense. "Mr Lea has a more ready way. He swallows a formula and then judges the universe and thus performance he calls Christian Science." Shorter pieces such as those on "baby shows" and "the telephone in medical practice"

¹ *The Radiography of the Chest*. Vol. II. Non-tuberculous Affections. By Walker Overend. M.D. (Oxon.). B.S. (Lon.). London: W. Heinemann (Medical Books) Ltd. 1928. (Demy 8vo pp. vii + 196. 124 figures. 2s. net.)

² *Practical Guide to Diseases of the Throat, Nose, and Ear*. By William Lamb. M.D. Fifth edition revised by Frederick W. Svedenhorn. M.D. C.M. London: Baillière Tindall and Cox. 1927. (Cr. 8vo pp. xvi + 450. 81 figures. 31 plates. 12s. 6d. net.)

³ *Short Essays on Medical Topics*. By C O Hawthorne. M.D. London: J. Bale, Son and Dantel's. Ltd. 1928. (Cr. 8vo pp. iv + 245. 4s. 2d. net.)

"sudden greyiness of the hair," and on "the training of memory," illustrate the wide range of Dr Hawthorne's interests. This is, in brief, a collection of well written and thoughtful papers on medical matters and the medical life—not to be looked through once and put aside, but kept in a handy place for occasional reading, with other books which are opened with expectation and studied with profit.

ENCYCLOPAEDIC OBSTETRICS

THE appearance of DeLee's *Principles and Practice of Obstetrics* in its fifth edition is a sure sign of the regard in which the book is held in the medical centres of America. The author may again be congratulated on what is truly a monumental work. The term textbook is inadequate, encyclopaedia would be a more apt description for a book of some eleven hundred pages, in which each chapter contains a great deal printed in small type in addition to the ordinary text. The practice of inserting "small type" paragraphs is of doubtful value, as important matter may be overlooked by the student—as, for example, in the chapter on placenta praevia. That so large a volume is beyond the province of the undergraduate is recognized by the author himself, as shown by his advice to the student in the preface. Here the student is urged to confine his attention to the "high lights," and to leave the rest of the work till after graduation. Even allowing for this attitude, there appears to be included considerable matter that might have been omitted without impairment to the value of the book.

The high incidence of maternal mortality and morbidity is ever before the mind of the author, and the principles of treatment enunciated are well calculated to improve the general standard of midwifery practice. To steer a happy course between conservatism and active intervention is frequently no easy task, but the teaching here propounded should enable that task to be of easier accomplishment.

The preparation of the volume has involved an immense amount of labour in searching through current literature, and the work gains in interest by the inclusion of references given at the end of each chapter. A feature of all American textbooks is the clarity of the illustrations. In this regard DeLee's book is no exception, for the many included are in themselves an education. As a work of reference the volume can be commended, for the author's endeavour to make it "an ever present help in time of trouble" has been attended with distinct success.

PHYSICAL CHEMISTRY AND BIOPHYSICS

FOR the student of medicine—whether he be practising, or still attending wards and lectures—one of the most difficult problems is the co-ordination of the facts with which he comes into contact, and the fitting of them into the mental picture which he has of his subject, so that they cease to be mere information and become knowledge. We venture to suggest that Professor STEEL's *Physical Chemistry and Biophysics* will prove of real help to anyone who wishes to grasp the relationship of the more recently acquired knowledge of the nature of matter to the biological problems with which the physician has to deal. It has for some time been clear that the newer conceptions of atomic structure and molecular constitution, and of the nature of the energy exchanges involved in chemical reactions, must affect, in quite a fundamental manner, the way in which we regard biological phenomena. It has, however, not been altogether easy to follow the development of current theories. To the uninitiated the technique of the physical laboratory is unfamiliar, and the terminology difficult, and apt to be alarmingly mathematical.

The first few chapters of Professor Steel's book give a

lucid explanation of some of the most important discoveries that have been made in the last few years in the realm of atomic physics. He commences with a brief historical account, starting with Dalton's work, he carries his reader to the researches of J. J. Thomson and Rutherford. He explains the birth and the development of the electron theory, its relationship to radio activity, and the physical principles of x rays. Such questions as the theory of isotopes and the quantum theory are briefly and very clearly discussed. It is hardly necessary to emphasize the importance of these matters for the biologist in general, and for the medical man in particular. Radiant energy of every sort is being pressed, often perhaps inadvisably, into the service of medicine. Only a clear grasp of the physical principles involved can ensure a proper discrimination in the employment of therapeutic agents of this type. To be ignorant is to surrender one's judgement. As a second example—the conception of enzyme activity lies at the root of our ideas of the nature of living matter. Recently there have been signs that Fischer's "lock and key" hypothesis, helpful as it has been, is being replaced by more exact conceptions. Such conceptions are based on the electrical theory of matter, in that they suppose that in certain conditions electrons may be displaced from molecules by external fields of force—for example, at certain active centres at a surface—and their displacement, by altering the electrical balance of the molecule, renders it "activated" or ready to undergo a chemical change. Specificity is vested, not in a chemical substance, but in a field of force having definite form and properties.

The remainder of Professor Steel's book is devoted to matters which are for the average reader more familiar territory. The subjects include the energy exchanges of the animal body, the properties of solutions, hydrogen ions, colloids, and cell membranes. They are discussed with admirable clearness, and with a peculiar insight for what is important and fundamental.

PENTAVALENT ARSENIC COMPOUNDS

IN his small book on oral chemotherapy with arsenic, Dr KURT HEYMAN gives an interesting history of the use of stovarsol in the treatment of syphilis. Dr LEVADITI, in a preface, points out the importance of this drug, which has been used with success not only in the prevention and treatment of syphilis, but also in amoebic dysentery and many varieties of trypanosomal infections. The author recalls the fact that Ehrlich made extensive experiments with pentavalent as well as trivalent arsenic compounds, and that stovarsol was number 564 in his well-known series, but that the inability of some of the pentavalent compounds to produce optic atrophy diverted his attention to the trivalent compounds. This fear of optic atrophy has been shown to be unfounded in the case of stovarsol, but Dr Heymann recalls that this defection of Ehrlich's interest at a critical point in his research has influenced the whole subsequent development of the chemotherapy of syphilis. The author shows that stovarsol is efficacious as a prophylactic against the development of syphilis, and that it is also of special value in the treatment of neuro-syphilis. The outstanding merit of the drug is that it can be given orally, and that it is actually more potent when given on an empty stomach than when injected. It produces only minor toxic effects, such as slight fever, purgation, and rashes, and these can be controlled by administration of sodium hyposulphite. Dr Heymann claims that it is possible to treat syphilis satisfactorily by intramuscular injections of bismuth combined with stovarsol by the mouth, and he remarks on the great advantage to the patient of avoiding intravenous injections. The evidence produced is scarcely adequate to support so drastic a change of procedure, but the suggestion is of interest as it indicates how important are the developments that may result from further study of the therapeutic properties of the pentavalent arsenic compounds.

INFECTIOUS DISEASES IN SCHOOLS

THE Medical Officers of Schools Association has recently issued the ninth edition of its *Code of Rules for the Prevention of Infectious and Communicable Diseases in Schools*.¹ The advance in our knowledge of the subject since the appearance of the last edition (noticed in the *Journal* of February 10th, 1923, p 251) has called for numerous changes and the incorporation of much new matter of which the most important are the pages dealing with the value of chemical disinfection and the part played by fomites in the spread of infection, the Dick, Schick, and Schultz Charlton tests, and the suggestion for a broader outlook on infectious diseases generally. Like its predecessors, the present edition of the *Code* has been drawn up with considerable care, and will be an indispensable guide to all interested in school hygiene.

NOTES ON BOOKS

DR HASTOR THOMSON is to be congratulated on the third edition of his little book on *Tuberculosis its Prevention and Home Treatment*.² It is one of the very few books on tuberculosis that could safely be put into the hands of a lay person. We think it rather a pity that in a popular work so much weight is placed on the infectivity of the sputum and so little on the cough spray. The available evidence suggests very strongly that the respiratory diseases, including pulmonary tuberculosis are transmitted largely by the fine droplets forcibly exhaled from the mouth or nose in loud talking, coughing and sneezing, and that dried dust is, at any rate under modern sanitary conditions, of comparatively small importance. It is really far more dangerous to permit anyone in a crowded railway carriage, theatre, cinema hall or other public place to cough or sneeze without a handkerchief in front of his mouth than it is to allow him to spit. Not that we think warnings against spitting superfluous—they are obviously not—but the time has come when the public should be instructed in the dangers of the cough spray, and taught that both spitting and coughing are to be avoided in public.

The new edition of *The International Handbook of Child Care and Protection*,³ the third of the series, has like the two earlier issues which bore a slightly different title been prepared by Mr EDWARD FULLER, editor of *The World's Children* under the auspices of the Save the Children Fund. Its aim is primarily to provide a record of conditions concerning matters affecting children—child welfare and education, juvenile employment and juvenile delinquency, marriage, divorce and legitimacy—in the 300 political units from which it has been possible to collect information. These details arranged geographically, occupy the greater part of the volume and apart from their obvious value, afford material for an absorbing study in contrasts, bringing to light the much more than nine and forty ways in which the nations have seen fit to arrange—or have blundered into arranging—their social affairs. Special articles deal with the policy of the Save the Children Fund, the refugee problem in relation to children, and religious laws and the family in the Roman Catholic, Jewish, and Mohammedan faiths. There is a useful directory of international organizations concerned with children, a statistical section tabulating where possible the main facts reported in the various national units, and a bibliography of works published between 1925 and 1927. The general index, an important feature in such a publication, appears to be adequate and well arranged and the work as a whole should prove exceedingly useful to those interested in its subject matter.

The new edition of Mr H C H CANDY'S *Manual of Physics for Medical Students*,⁴ which is designed to provide candidates with the information required for their first examination in this subject, has been revised throughout. Additions have been made to many of the sections, the main new feature being the incorporation of the kinetic theory of gases which

¹ *Code of Rules for the Prevention of Communicable Diseases in Schools*. Issued by the Medical Officers of Schools Association. Ninth edition. London: J. and A. Churchill, 1928. (Demy 8vo pp 74 2s 6d. net.)

² *Tuberculosis its Prevention and Home Treatment*. By H. Hastor Thomson M.D. D.P.H. Third edition. Oxford Medical Publications: London: Milford Oxford University Press, 1928. (Cr 8vo pp xi + 99 6 charts. 2s 6d. net.)

³ *The International Handbook of Child Care and Protection*. Compiled from official sources by Edward Fuller. Third edition. (Cr 8vo pp xiii + 646 10s. 6d. net.)

⁴ *A Manual of Physics Theoretical and Practical for Medical Students*. By Hugh C. H. Candy B.Sc. Lond. F.I.C. Third edition enlarged. London: Cassell and Co. Ltd. 1928. (Fcap 8vo pp. viii + 387 299 figures 1 plate. 7s. 6d. net.)

is now included in the syllabus of the Conjoint Examining Board. Experimental illustrations have been employed throughout the text. In spite of additions, however, this little volume remains of reasonable size—it is conveniently arranged and clearly written.

LAMBOURNE and MITCHELL'S *Qualitative and Volumetric Analysis for Medical Students*,⁵ is a small volume providing candidates for the premedical examination of the Conjoint Board with all the coaching they need in practical chemistry. Brevity is of the essence of lucidity and the shortest description is the easiest to remember. That is why textbooks of condensed memoranda to which class this little volume belongs are so much favoured. It is not pretended that they teach all that science requires, but if the student has had a proper course of lectures he will profit more from short directions than long ones. Lambourne and Mitchell's book is one of the best of its kind.

Income Tax Up to Date,⁶ is a brief but clearly arranged guide to the various allowances and reliefs provided by the Income Tax Acts. Our fiscal code is so scattered over the various Finance Acts that a succinct exposition is often desirable and this little publication by Mr H. J. GULLY is well designed to fulfil that object. It does not however afford much assistance in the calculation of the amount of income to be returned for assessment—which is usually the chief source of difficulty to taxpayers.

⁵ *Qualitative and Volumetric Analysis for Medical Students*. By H. Lambourne M.Sc. F.I.C. and J. A. Mitchell, M.Sc. Oxford Medical Publications. London: Milford Oxford University Press, 1928. (Cr 8vo pp v + 64 5s. net.)

⁶ *Income Tax Up to Date*. By H. J. Gully, F.C.A. Fourteenth year. London: *The Financial News*, 1928. (5½ x 8½ pp 20 9d.)

PREPARATIONS AND APPLIANCES

THROAT, EAR, AND NOSE INSTRUMENTS

DR G. W. MONEY (London) has devised the following modifications of certain well known instruments which have been found to be very useful.

Tonsil Volcrillum Forceps—This has been adapted from Tilley's instrument the chief difference being that while the jaws have a similar curve they grasp the tonsil longitudinally instead of horizontally. Moreover the spring catch has been replaced by the ordinary cross-over shanks which are fitted with a ratchet at the handles by means of this a good grip is retained throughout the operation. The instrument has also been considerably lengthened, being 9½ inches as compared with the 8 inches of that of Tilley. The bows of the forceps are so made that a snare can easily be applied.

Tonsil Volcrillum Forceps.

Mastoid Retractor

Nasopharyngoscope.

Mastoid Retractor—The mastoid retractor is a modification of that of Wagener; it gives a wide field the shanks being bent to allow of this. The base of the instrument is curved so as to lie well back out of the field of operation. It is opened and closed by a ratchet action which is easier and quicker in use than the ordinary screw.

Nasopharyngoscope—The illustration shows a Holmes instrument connected with a handle containing a battery, as used with the May's ophthalmoscope. The instrument being self-contained has been found to be more convenient than nasopharyngoscopes comprising more than one part.

These instruments were made by the Medical Supply Association, Ltd., 167, Gray's Inn Road, W.C.1.

NOX FLAM EYE SHIELDS

Messrs Solport Brothers Limited of whose Fortin's non flamm eye shields a notice appeared in the *Journal* of July 14th (p. 57) inform us that they are taking prompt measures to adopt our suggestion for a series of small perforations parallel with the upper border of the shield.

HEALTH OF LONDON

REPORT FOR 1927

THE progress of public health in London during 1927 is set forth by Dr F N Kay Menzies in his reports as county medical officer of health and school medical officer, which are contained in volume III of the annual report of the county council.

Births and Deaths

The population of the County of London in the middle of 1927 is estimated at 4,550,000, including 9,000 non-civilians. The births during the year were 73,263, giving a birth rate of 16.1 per 1,000, which is lower than last year and the year before. Since 1921 the number of births has been decreasing at the rate of 4,000 annually. The deaths were 55,170, or 12.1 per 1,000. This rate is higher than in the two preceding years, the influenza outbreak at the beginning of the year is held to be responsible. Deaths due to diarrhoea were considerably below the average.

Small-pox

Five cases of small-pox occurred in the administrative county, of which two were fatal. Three patients were unvaccinated at the time of infection, one, described as vaccinated, showed no scar, and one, 54 years of age, had been vaccinated in infancy only. One of the fatal cases belonged to the unvaccinated group, the other was the case without a scar. Four of the five patients are believed to have been associated, directly or indirectly, with a conedental outbreak in Hendon. The fifth was a man who had tramped from Yorkshire and was discovered in the Paddington casual ward, his illness was of the mild provincial type. These five cases occurred in 1927, the year dealt with by the report. During the first three months of 1928 there were about fifty cases in London, mostly among vagrants or indigent persons.

In December, 1927, the Metropolitan Asylums Board adopted revised arrangements for the removal of small-pox patients to hospital. When the Board receives an application from a medical practitioner for the removal of a patient certified to have small-pox, it removes the patient and at the same time notifies the medical officer of the borough concerned. The medical superintendent of the hospital informs the borough medical officer of his view of the diagnosis. If the patient is retained for observation the borough medical officer is given facilities for visiting. When a medical practitioner applies for the removal of a patient whom he is not prepared to certify as suffering from small-pox, the Board refers him to the borough medical officer. Removal is not effected without a certificate from the applicant practitioner or without a request from the borough medical officer to have the case admitted for observation.

Puerperal Fever

The mortality from puerperal fever is much lower in boroughs with poorer class populations than in those occupied largely by the well-to-do. During the five years 1921-25 the average annual death rate per 1,000 births was 0.88 for a poorer group of boroughs and 1.80 for a well-to-do group.

Anthrax

Five cases of anthrax were notified during 1927, but two were not confirmed. The three patients with definite anthrax, and one other resident outside London, had been engaged in handling the carcasses of two elephants which had died at the Zoological Gardens. All received anti-anthrax serum and recovered. Twenty-nine other patients who had come into contact with the elephants received successful prophylactic doses.

Encephalitis Lethargica

The notifications of encephalitis lethargica were 142 as contrasted with 600, 293, and 224 in the three preceding years. Suitable patients with post-encephalitic symptoms and under the age of 16 are dealt with in the encephalitis lethargica unit at Winchmore Hill. The work there has shown that, while no positive curative results can be expected, many children exhibit considerable improvement.

The unit has justified its existence, if only as a clearing house and observation station, patients suffering from the characteristic physical disabilities, including paralysis and Parkinsonism, may receive skilled attention, and children whose mental condition unfits them for ordinary outside life may be kept under observation. For the past three years officials of the council's health department have followed up surviving cases of encephalitis lethargica, whether notified or not. The results in 528 cases, covering the years 1918 to 1926, are stated in a table, which indicates that of 217 patients under the age of 16, 85 are still affected, while of 311 cases over this age 200 are still affected.

Cancer

The deaths from cancer during the year were 6,774, with a death rate of 1.49, which is higher than in the two preceding years. The cancer mortality among women in London has been decreasing in the last ten years. From a survey of the cancer deaths during 1911-20 it emerges that the most frequently fatal cancers in males are those of the alimentary tract above the diaphragm, while the most frequently fatal cancers in females are those of the reproductive system. Cancers in other parts of the body appear to have an approximately equal sex mortality. It is suggested that the female cancer mortality rate in London will continue to decline, while that of males will increase further for some time.

Mothers and Infants

Of 5,000 duly certified midwives with London addresses 870 gave notice of intention to practise in the county during the whole or part of the year. Seventy-seven infringements of the rules of the Central Midwives Board were reported. 41 were slight, and 29 were dealt with by written caution. Four midwives were interviewed by the committee, and one was reported to the Central Midwives Board. There were 267 notifications of puerperal fever and 892 of puerperal pyrexia. In the course of an inquiry as to 186 cases of puerperal pyrexia the most frequently attributed causes were influenza 35, respiratory disease 20, septicaemia 20, retained membranes 9, urinary infection 8, pelvic infection 7, breast inflammation 6, digestive disease 5, and phlebitis 5. In a number of cases no cause had been diagnosed. Of 814 notified cases of ophthalmia neonatorum 60 per cent were in the practice of midwives. Of the cases which occurred in the practice of midwives 475 were completely cured. Of ophthalmia neonatorum during the year there were 251 cases, in 16 instances there was group infection. The average date of onset was six to seven days after birth. In six cases where the serum from unbroken blebs was examined the organism present was *Staphylococcus aureus* in pure culture.

Chemical Branch

Among matters dealt with by the chemical branch of the Public Health Department were the killing of trees in a public park by acid sulphate of iron washed by rain out of ashes used for making up a playground, the filling up of the cavity of a hollow brick wall at one of the council's housing estates by the giant puff ball, *Lycoperdon giganteum*, and the use of copper sulphate and chlorine to maintain the clarity of water in swimming baths. It is estimated that the amount of impurity introduced into a bath by a not too clean adult is 0.8 gram of nitrogen in all forms and 1.4 grams of chlorine.

Desks in Schools

In the account of school hygiene, which forms chapter IV of volume III of the report of the London County Council, it is claimed that the London dual desk has given in practice as good results as can be attained. This is largely due to the fact that the desks are supplied in seven graded sizes. At one time the desks were made with foot-rests, but many years ago, on the advice of the school medical officer, the foot-rests were discarded. Recently the question of foot-rests was revived by certain head teachers. The arguments advanced in their favour were (1) that they gave an alternative position for the feet, (2) that they allowed quicker drying of wet foot gear, (3) that they were less noisy, (4) that they ensured a better

sitting posture, and (5) that they strengthened the desks. Dr N Dobbie reported upon these arguments as either erroneous or unsubstantial, and it was decided to take no action. Despite the seven graded sizes of desk misfits occur, especially in the upper standards, where the range of difference in height of the children may amount to as much as 18 inches. The suggestion is offered—and it seems self-commended—that, as soon as pinnacles have been made, the children in each class should be paraded, “dressed” according to sizes, and, by means of exchanges with other classes if necessary, fitted with proper desks. The guiding rule is that the height of the desk sent above the floor should be approximately two-sevenths of the child's stature. This is, or should be, an easy rule to apply.

Dental Condition

An interesting report of progress is presented with regard to the dental condition of school children. In 1906 the late Mr C E Wallis carried out a careful inspection of the teeth, gums, tonsils, throats, and glands of 245 children in the Michael Faraday school at Waltham. The conditions which Mr Wallis revealed prompted the council to set on foot its now existing school dental service, which treats 125,000 children yearly. To the question, Is the service justified by its results? an affirmative answer is given. In 1927, at an inspection of the same Michael Faraday school, which still remains in Waltham, an examination was made of children in the same sex and age groups as in 1906. In every group and in the total number the frequency of carious teeth, both temporary and permanent, was lower in 1927. In 1906 the average number of carious teeth per child was 7.4, in 1927 it was 2.10. In 1927, 47 children, or 21.5 per cent, were free from dental defect and oral disease, in 1906 not one. The reduction of cases of enlargement of the submaxillary glands from 218 in 1906 to 65 in 1927 tells the same tale. It is a story of work which was well worth doing, though complete prophylaxis, as Dr Menzies regrets, is still far off. Schools differ considerably from one another in the response of parents to the intimation that dental treatment for a child is necessary. In one school, where 58 children were referred for treatment, there were 31 refusals, a number of parents taking the view that the teeth were “not bad enough yet.” In another school, where the head teacher had army experience, 100 per cent of treatment recommended was obtained, both dental and medical.

Rheumatism in Childhood

From the commencement of the rheumatism scheme in November, 1926, until December 31st 1927, a total of 535 nominations was received for institutional treatment for rheumatism in childhood. The children were treated in the subacute and rheumatic fever units at St Mary's Hospital, Carshalton, and in the subacute unit at Highwood Hospital, Brentwood. An analysis of 100 cases revealed that 20 were pure subacute rheumatism, 6 were pure rheumatic fever, and 9 were pure chorea. Of the remaining cases 37 combined the subacute phase with rheumatic fever, 19 were subacute rheumatism with chorea, 1 was rheumatic fever with chorea, 6 combined all three types, and in 2 there was no previous history. The high proportion of chorea among the 100 cases is possibly due to the fact that the group was weighted with advanced cases. A peak of incidence appeared about the age of 7, and another between 11 and 14. Seventy-nine of the children were below average nutrition, and 89 showed pallor. Forty-three children had enlarged tonsils and 40 had undergone tonsillectomy, the enlarged tonsils were seldom accompanied by adenoidal growths. Thirty-five of the children came from slums, and 53 more were borderline slum dwellers.

Diphtheria Carriers Clinic

With a view to the more intensive treatment of diphtheria carriers the council, in November 1926 sanctioned an arrangement with Guy's Hospital for dealing with such carriers at a special clinic attached to the hospital. These patients, though harbouring virulent diphtheria, are themselves immune, they are unsuitable for admission to infectious diseases hospitals or to ordinary

out-patient departments of the general hospitals. It is now becoming well known that the carrier state is always associated with a pathological condition of the nasal mucosa, fauces, or pharynx. Up to December 31st, 1927 a total of 115 children had been dealt with at the clinic. 56 were able to return to school in less than four weeks, 32 in four to eight weeks, 13 in eight to twelve weeks, 9 in twelve to sixteen weeks, and 1 was under treatment for nineteen weeks. The remainder were still under treatment. Much benefit has been derived from the special treatment of the children, and the council has authorized the extension of the scheme to other hospitals.

Epidemic Jaundice

In April and May an outbreak of jaundice occurred in a school in Tooting involving thirteen cases, and in October and November further cases appeared in some schools in Camden Town. The attacks began with vomiting or anorexia, rapidly followed by jaundice lasting from one to four weeks. The stools were clay-coloured and the urine dark. There was little evidence of household infection. Examination of the urine for *Leptospira icterohaemorrhagiae* proved negative, there were no cases of influenza at the time and the disease was presumed to be catarrhal jaundice.

Non Angli sed Angeli

Other sections of much interest in the school report are those dealing with chronic invalidity, personal hygiene, physical education, instruction in hygiene, open-air schools, nursery schools, poliomyelitis, and defectives. The general chapter on public health and chapters on main drainage and housing complete the annual report. The ideal towards which Dr Menzies aspires are declared by him in the following words, which may fitly close this notice: “Fourteen hundred years ago the children of the south-eastern part of England were famed throughout the civilized world for their beauty, their health, and their physique. The industrialization and urbanization of the nineteenth century, combined with the pursuance of the policy of *laissez-faire*, sadly discoloured the beauty of the race's childhood. We are now in the process of emerging from that nightmare. Good housing, better education, playing fields—these three are the dominant needs of the child and parent of England's great metropolis. Already and increasingly going into our schools, the improving appearance of our London children brings back the echo of the words of Pope Gregory, *Non Angli sed Angeli*.”

ROYAL MEDICAL BENEVOLENT FUND

At a recent meeting of the committee of the Royal Medical Benevolent Fund thirty-seven applications for assistance were considered and £520 was voted to thirty-two cases. As the holiday season approaches requests are received from widows and others for help towards the holiday expenses of children of medical men, and an appeal is made to all who sympathize with the children's needs at this time to support this work by sending subscriptions to the Honorary Treasurer, 11 Chandos Street, Cavendish Square, London, W.1. The following cases include examples of holiday appeals and others.

Mrs. X wife of M.B. Lond. who is in a mental home as a free patient has charge of three children with no income except that from her own needlework. One child, a girl of 12, is educated by her godmother. The Fund pays school fees for a boy of 9, the third child is at home. The applicant broke down in April and has been able to do so little work since that the prospect of the summer holidays is a nightmare as regards finance. A grant of £7 10s was voted.

M.R.C.S. died in 1921 leaving five children aged 4 to 12 years, one is at Epsom College, one at a girls' school and three at orphanages. They are dependent on relatives who are unable to contribute. Fund voted £15 for children's holidays.

M.M.S.B. aged 70 after twenty-one years in practice broke down in health in 1920, now suffering from bronchitis and diabetes and unable to work without means except 15s. a week which his wife earns as a cook housekeeper. Voted £40.

L.R.C.P. and S.E.d. aged 68 whose wife aged 66 is delicate had to give up regular practice twenty-four years ago, since then he has worked as locum tenens. He is handicapped by ill health and during the last nine months has been unable to work and has got into financial difficulties. Voted £40.

The Royal Medical Benevolent Fund Guild still receive many applications for clothing, especially for coats and skirts for ladies and girls holding secretarial posts and suits for working boys. The Guild appeals for second hand clothes and household articles. The gifts should be sent to the Secretary of the Guild, 58 Great Marlborough Street, W.1.

THE OPIUM PROBLEM

DEVELOPMENT OF INTERNATIONAL CONTROL

The Opium Problem,¹ by Dr Charles E Terry and Mildred Pellens, is a formidable compilation of over a thousand pages, prepared for the Committee on Drug Addictions of New York, which was formed in 1921 as the outcome of several conferences on the narcotic drug question. The committee sought to ascertain the extent, causes, nature, and treatment of "chronic opium intoxication." The method adopted was to review the medical and other literature on the subject, to make a digest of the relative laws, regulations, and international conventions, and to collate the replies to questionnaires issued to medical and administrative authorities throughout the United States. In fourteen chapters the compilation deals successively with the extent, pathology (somatic and psychic), symptomatology, and treatment of narcotic drug addiction, and with the national and international control of the traffic in opium and its derivatives.

The materials for arriving at the number of addicts in the United States are admittedly and necessarily unreliable. Estimates varying from a hundred thousand to a million have been put forward, but most, if not all, agree that there is "a major medico-social problem" to be grappled with. An interesting sketch is given of the history of the use of opium as a drug from the earliest times, and of the discovery and extraction of its alkaloids in the early nineteenth century, followed by the introduction of hypodermic medication. At first it was generally asserted that the injection of morphine was not productive of the same addiction as opium eating or snoring was liable to occasion, but since 1870, as shown by the writings of Clifford Allbutt and others, the erroneousness of such teaching has been overwhelmingly demonstrated. So again, in 1898, when Dresser in Germany produced heroin or diacetyl-morphine, the claim was made that the new alkaloid possessed all the advantages of morphine and opium without their dangers. Since 1903, however, evidence has accumulated to prove it also to be a perilous drug of addiction, moreover, it is largely resorted to by "the underworld" and the criminal classes.

A careful review of recent researches on the pharmacology of opium and its derivatives and their physico-chemical effects leads the authors to the conclusion that no theory yet advanced sufficiently explains the exact nature of the somatic and psychic phenomena observed, and they accordingly urge further research—clinical, psychiatric, neurological, and experimental—into the pathology of chronic opium intoxication. As regards the types of person apt to become addicts, the conclusion is reached that this liability is "not restricted to any social, economic, mental, or other group," and "that there is no type which may be characterized as the habitual user of opium, but that all types are actually or potentially users."

Under the head of treatment the arguments for and against complete and immediate withdrawal of the drug, put forward by a long array of writers on the subject, are cited, but "the conclusion reached from the material reviewed is that, for the most part, the treatment of this condition has not emerged from the stage of empiricism. The various methods described in general indicate that the basis of the majority of them is merely the separation of the patient from the drug."

The remaining chapters deal with "control" of the drug traffic—international, national, and municipal. In view of the approach of the coming into force² of the

Geneva Convention of 1925, which implements in certain respects the Hague International Opium Convention of 1912, it is useful to have a resume of the efforts made to effect the international control of the traffic in drugs of addiction. According to the late Dr Hamilton Wright, the United States, as early as 1833, entered into a treaty with Siam forbidding Americans to engage in the opium traffic with the Siamese. In 1844 a similar treaty was entered into with China, but by the Treaty of 1858 the restriction on Americans trading in opium was relaxed. By an American-Chinese treaty of commerce in 1880 the import of opium into China by Americans or into America by Chinese was forbidden, and by a later pact in 1903 the importation of morphine into China, and also the manufacture of morphine and instruments for its injection, except for medicinal purposes and on payment of a tariff duty, were prohibited. When the United States assumed control of the Philippine Islands the serious abuse of opium among the natives led to the appointment of a commission, whose report resulted in legislation prohibiting the importation of opium into the Philippines except for medicinal purposes. Arising out of the Philippine Commission came the suggestion of Bishop Brent to President Roosevelt to invite the Powers interested in the Far East to confer with a view to investigating the opium trade and the opium habit.

Thus arose the Shanghai Commission of 1909, attended by representatives of Great Britain, the United States, France, the Netherlands, Germany, China, Japan, Persia, Portugal, Italy, Russia, and Siam. The report of this commission sufficed to show that drug addiction was not confined to the Far East, but was in fact world-wide, that the unrestricted sale of morphine constituted a grave danger, that drastic measures should be taken to control its manufacture and sale, and that other derivatives of opium were liable to similar abuse. The gradual suppression of opium smoking was also urged, and the need for control of the export and import of opium and its derivatives was emphasized.

The Government of the United States followed up the Shanghai Commission by proposing an international conference at the Hague to conventionalize the findings of that commission. Meanwhile, the British agreement with China to bring to an end the Indo-Chinese trade in opium was taking effect, and the British Government, in consequence, showed some reluctance to take part in the proposed conference, but eventually agreed to participate on the condition that the growing evil of the illicit use of morphine and cocaine should be drastically dealt with. The outcome of the first International Opium Conference at the Hague, presided over by Bishop Brent, was the Hague Convention of 1912, which, by international action, sought to restrict the production, sale, distribution, import, and export of raw opium, to suppress opium smoking, and to limit the use of morphine, cocaine, heroin, etc., to medicinal and other legitimate purposes. The Dangerous Drugs Acts of 1920 and 1923 gave effect to the convention in Great Britain, while the Harrison Narcotic Act of 1914, amended in 1918, 1926, and 1927, provided similar legislation for the United States.

After the war (experience during which had indicated greater need for control of the traffic in narcotics) the Treaty of Versailles and the other peace treaties provided for the adhesion to the Hague Convention of Powers which had previously abstained, and the League of Nations took cognizance of the opium traffic. The story of the measures taken in this connexion by the League Council and Assembly and the Advisory Committee on Opium is related with much documentation, and the proceedings and results of the two Geneva Conferences of 1924 and 1925 are duly chronicled, bringing the history of international control of addiction up to the end of 1927. If the work of Dr Terry and Mildred Pellens adds little that is new to the discussion of the opium problem, it brings together in a useful and handy form material derived from many countries over a series of years, and provides the student of this complex social question with abundant information in regard to the pathology, therapeutics, and efforts at administrative control of so-called habit-forming drugs.

¹ *The Opium Problem*. By Charles E. Terry M.D. and Mildred Pellens of the Committee on Drug Addictions in collaboration with the Bureau of Social Hygiene Inc. New York. The Committee on Drug Addictions 1923. (M. d. Soc. pp. xvi + 1042. Illustrated.)

² The provisions of the Convention of 1925 were discussed in the *British Medical Journal* of July 21st (p. 117). We published on August 25th (p. 351) a Home Office communiqué announcing that the Convention will come into force on September 26th and describing the consequent changes which will take effect on that date in the regulations governing the traffic in dangerous drugs in Great Britain.

SATURDAY, SEPTEMBER 8TH 1928.

LATE RESULTS OF OPERATION FOR CANCER OF THE BREAST

THESE are something stimulating in a bird's eye view of an association of active efforts directed to a common objective. The series of reports which has emanated from the Departmental Committee on Cancer since its institution by the Ministry of Health in 1923 is such a survey. These documents indicate the stages in a campaign, they show that real progress is being made and they encourage the hope that still more definite messages of success may be looked for in the not distant future. Thus in 1924 an immense amount of information on the surgical treatment of cancer of the breast was collected, and an exhaustive report was issued by Dr. Janet Lane Claypon, who received guidance in the statistical investigation from Professor Major Greenwood. When referring to this valuable piece of work at the time of its publication¹ we remarked that this demonstration of the effectiveness of surgical operation should convince even the most sceptical. A year and a half later Dr. Lane Claypon produced a second report on cancer of the breast, relating more particularly to the statistical study of the antecedents of mammary cancer. We considered this report likely to be even more useful than its predecessor, in that conclusions which had previously been little more than impressions were now fortified by the evidence of exact figures.² A third report³ by Dr. Lane Claypon has just been published, dealing with the late results of operation for cancer of the breast, and based on an analysis of 2,006 cases occurring in the practice of the general hospitals of eight county boroughs of England and Wales during the period 1910-21: the cities under review were Birmingham, Bristol, Cardiff, Leeds, Leicester, Newcastle, Nottingham, and Manchester.⁴

It will be remembered that in its earlier efforts to assess the value of surgical operation in cancer of the breast a statistical analysis was given by the Departmental Committee of the data contained in medical literature throughout the world. The number of reporters was comparatively small, few were English and most of them recorded their results for a period no longer than three years after treatment. This evidence which formed the substance of the first report was supplemented by the second report: a further step has now been taken, rendering it possible to ascertain the fate of many patients submitted to operation for cancer of the breast for periods of three, five, and ten years after operation. The primary object of the present investigation has been to ascertain the results of operation in relation to the stage of the disease for which the operation was performed, the nature of the operation, and the type of tumour present as identified by routine examination.

In a prefatory note to the present report Sir George Newman remarks that the type of growth as usually

classified appears to have the least influence on the success or otherwise of the operation, the stage of the disease, and the completeness with which the operation is performed, are of relatively outstanding importance in securing the best results. The most vital factor in success, therefore, is that treatment should be applied as early as possible. Thus it is shown in the report that the percentage of survivals to ten years when treated in the early stages is 73, while when the disease has spread beyond the breast the percentage falls to 13. Yet of patients undergoing operative treatment at hospitals, not more than 25 per cent are in this early stage. The average interval allowed to elapse, even in early cases, between the first notice of the condition and the patient seeking treatment is as long as seven months. Sir George Newman emphasizes therefore the prime need for fuller realization on the part of the public as a whole, and perhaps of the medical profession too, of the fact that a lump in the breast of an adult woman calls for diagnosis and treatment without a moment's avoidable delay.

The operations concerned were performed by 113 different surgeons. In 1,642 cases carcinoma was verified by pathological examination, while 364 cases which were believed to be carcinomata, though no pathological confirmation was obtained are considered separately in the report. Sarcoma was diagnosed in 35 cases, and endothelioma or perithelioma in 19. There were 36 recurrences after previous operation elsewhere, in 41 instances the operation was stated to have been palliative only, and these cases have therefore been omitted from the conclusion. Analysing the clinical data Dr. Lane Claypon shows that the age of hospital applicants does not follow the same curve as that of the mortality rate, since the number of these applicants falls off rapidly after middle life, whereas the mortality rate continues to rise. The fertility of the married women was below the average and complete absence of lactation occurred even more often than had been found in previous investigations. Growths were fairly evenly distributed between the sides of the body, but such preponderance as existed was towards the left side. This contrasts with the report for 1924 in which no difference at all was found in the two sides. The outer and upper quadrant of the breast was the site most frequently affected. As regards the delay in seeking treatment Dr. Lane Claypon reports that if only those women are considered who gave an alleged duration of their symptoms of three years or less, the mean alleged duration is roughly nine months for all stages of the disease, and is just over seven months even for those patients in whom the disease was still local. No reasons are offered for this delay, which seriously reduces the patient's chances of survival. The net survival rates were as follows: When the growth was still local as shown by pathological examination of the axillary glands the rate at three years was 85.0, at five years 78.5, and at ten years 73.3. When the axillary glands had been invaded the rate at three years was 40.7, at five years 24.7, and at ten years 13.0. With still more extended growths the rate at three years was 35.2, at five years 21.9, and at ten years 12.7. In this calculation deaths from operation were counted as deaths from cancer, but the total operative mortality was below 3 per cent.

Contrary to the general clinical impression the prognosis in women under the age of 40 who had been operated upon at an early stage of the disease is shown to be definitely more favourable than that for older women. In the later stages of the disease there was little difference in the survival rates, but such

⁴ The first report on Leeds was noticed in the *British Medical Journal* of August 14th 1926 p. 318.

slight difference as there was favoured the women over 60 years of age. No significant difference was observed between the survival rates for growths of the cellular type and those of the scirrhous type, though duct, adeno, and colloid carcinomata had the more favourable prognoses. As regards the nature of the operation performed, good results followed in very early cases when the breast or even the tumour alone was removed, although there is, obviously, risk of incomplete removal. Operations involving the partial clearance of the axilla in early cases were attended by bad results as compared with those following the radical operation, even when the latter was performed in cases less early than those in which the conservative operation was employed. Cases of rapid dissemination, in the early stages, of cancer cells to other organs were rare. No support was obtained for the view that growths towards the inner side of the breast were more dangerous than those elsewhere. The excellent functional results obtained after radical operation showed convincingly that in most patients there was little detriment either personal or economic, following removal of the pectoral muscles. Dr. Lane Claydon concludes her report by insisting that a great reduction in the mortality rate from cancer of the breast at all ages up to and even over 70 would be effected if early and radical operation were undertaken more often.

RECENT MALIGNANT DIPHThERIA

GENERALLY speaking, the type of diphtheria which prevailed in this country during 1927 was not characterized by its severity. In England and Wales the case mortality amounted to 5.2 per cent, as compared with 5.8 and 5.9 respectively during the two previous years, and in London in 1927 there was a decline from 3.9 and 4.0 per cent to 3.15. Reports from the United States and the Continent, however, testify not only to a marked increase in prevalence, but also to the occurrence of an unusually malignant form of the disease. In New York City the total of 13,507 cases and 717 deaths during the year 1927 showed a notable increase over that of 1926 with 7,531 cases and 477 deaths, the lowest figures yet recorded for any year, presenting the contrast of an attack rate of 2.26 per 1,000 population and a death rate of 12 per 100,000 for 1927 as compared with only 1.27 per 1,000 attack rate and 8 per 100,000 death rate in 1926.

The steady fall in the diphtheria rates in New York of recent years has amounted to a difference of as much as 38.9 per cent in the case incidence between 1923 and 1926, which may have lent substance to the hope that immunization had been in some measure responsible. But as there are no less than two thirds of the one and a half million child population of New York under the age of 15 not yet immunized, this larger unprotected fraction, of roughly one million, would alone have afforded abundant and ready soil for the considerable increase in morbidity shown by the wave of epidemic which arose in the early part of 1927 in the city of New York and elsewhere and reaching its crest during the spring, maintained its force through the summer months till mid July. During that period of twenty-eight weeks the notifications totalled 9,112, averaging 325 per week, more than double those in the corresponding period of 1926, when only 4,218 cases—a weekly average of 150—were recorded. In the subsequent fourteen weeks, from July 17th to October 24th, the increase showed decided abatement, the excess over 1926 of the weekly totals amounting

only to 20, with a total for the fourteen weeks of 1,657 cases, as compared with 1,385 in 1926. In the final ten weeks of 1927 there was a further recrudescence, but considerably less than during the first half of the year, with an average of 85 per week in excess of the 1926 weekly notifications.

Similarly in Chicago, the total notified cases of diphtheria rose from 2,723, with an attack rate of 0.9 per 1,000 in 1926, to 5,182, a rise in attack rate nearly double, to 1.7 per 1,000 in 1927, and from the records available for the first half-year the diphtheria deaths more than doubled those for the first six months of 1926. At the Chicago Municipal Hospital the case fatality rate rose from 11.6 per cent in 1926 to 15.2 per cent in 1927. In Boston, too, diphtheria notifications increased from 995 in 1926 to 1,387 in 1927, an increase in attack rate from 127 to 177 per 100,000.

In Germany, reports from Berlin, Breslau, and other towns for the past two years have shown a considerable rise in prevalence, as well as in the case fatalities, which in old Berlin in 1926 reached the high figure of 17 per cent, as compared with 6 per cent in 1923, and has lately led to the adoption by the authorities of free immunization for the protection of the public. The exceptionally malignant type associated with the greater prevalence of the disease in the United States in 1927 and Germany in 1926 and 1927 has been marked by considerable glandular enlargement, the so-called 'bull neck,' with foul discharges from the throat and nose, and not uncommonly followed by cardiac and renal complications, with rapidly fatal toxemia. The severity of such cases and their failure to respond to prompt and early administration of antitoxin have been attributed mainly to secondary streptococcal infection, and it was only after combining diphtheria antitoxin with a polyvalent antistreptococcal serum that treatment proved successful.

Whereas this country has experienced comparative freedom in the past year from the severe form prevalent in America and Germany, reports from certain areas, however, such as Bristol and Leicester, have recorded its occurrence and sound a note of warning. In West Ham also the type of diphtheria experienced last year was more than usually severe (M.O.H. annual report 1927). At a meeting of the Fever Hospital Group of the Medical Officers of Health Society held at the end of April, a paper by Drs. H. S. Banks and George McCracken dealt with some 300 cases, including close on 10 per cent of the malignant type, successfully treated by the intravenous administration of antitoxin at the City Isolation Hospital in Leicester during the past two years. Their cases were classified in four groups in order of severity: (1) 27 malignant cases with severe adenitis treated with an average dose of 71,000 units given intravenously and 31,000 units intramuscularly, (2) 52 cases of lesser severity, which received 19,000 units intramuscularly, (3) 214 mild or moderate cases, to which 14,000 units were given by intramuscular injection, (4) 7 cases of laryngeal diphtheria. In the procedure of intravenous injection Dr. Banks recommended the use of a serum concentration of 1,400 units per c.c.m., administration occupying a period of twenty minutes, followed by injection of 4 minims of adrenaline to counteract the possibility of serum reaction. The advantages of the intravenous route were the rapidity of obtaining a maximum concentration of antitoxin in the circulation, which followed immediately, as compared with twenty-four hours by intramuscular injection, and three days' interval by means of subcutaneous inoculation—in all important

gain of precious time, when every hour saved may make all the difference to the patient. With reference to the size of the doses, as much as 140,000 units intravenously in a single dose has been given at Leicester without harmful effects, and even larger doses, up to 200,000 units, have been employed by Professor v. Bie in Copenhagen. As the result of intravenous injection it was claimed that the case mortality of the diphtheria patients in the Leicester hospital had been reduced from an average of 9.3 to 2.6 per cent. The number of diphtheria deaths in Leicester fell from 38 in 1926 to only 10 in 1927, representing a decline in the diphtheria death rate from 15 to 4 per 100,000. Moreover, the risk of complications, notably paralysis, had, it was stated, been considerably diminished.

This experience of the value of intravenous administration of antitoxin in large doses is, however, contrary to general opinion in this country, as held by E. W. Goodall and others, and in America by W. H. Park, who have asserted that doses in excess of 30,000 and 50,000 units are useless. It is of interest to note that the intraperitoneal injection of antitoxin has lately been advocated in America. Platon and Stewart of Minnesota found that one hour after treatment by this route the blood contained sufficient antitoxin to neutralize all the circulating toxin of even the most severe form of diphtheria.

INTERNATIONAL PUBLIC HEALTH

A SUMMARY has been issued recently of the proceedings at the extraordinary session of the permanent committee of the International Office of Public Health, held in Paris last May. Its appearance coincided sadly with the news of the death of Dr. H. Poterwin, who had been secretary of the office from its foundation in 1907 to 1926, when he was appointed director. Dr. Poterwin was highly esteemed for his brilliant services to international medicine and hygiene, his exceptional ability in summing up controversial questions, his wide outlook, and his genial personality. He was a member of the French Senate until last year, a professor in the Conservatoire des Arts et Metiers, and during the war gave valuable help in co-ordinating information about the health conditions of the different forces. He was taken ill shortly after the close of the Paris session in May. The practical importance of this session is to be found in the adjustment of details of quarantine procedure under the International Sanitary Convention of 1926. Model certificates of deratization or exemption from deratization—a word coined to denote the clearance of ships from rats—have been drawn up and have been adopted by two countries, Great Britain and France. Some provisions of the Opium Convention have been examined, and the conclusions arrived at have been sent to the Health Committee of the League of Nations. The work of the permanent committee is naturally mainly concerned with such international agreements, but the committee furnishes also a convenient body for the pooling of experience in matters of epidemiology. Thus the report records sundry observations made in various recent epidemics of yellow fever, cholera and plague. There is a note on the continued prevalence of mild smallpox in England, the freedom of the large ports except Newcastle from this disease, and the relative frequency in Holland of post-vaccinal encephalitis. The researches of Dutch, English, and German experts are tending to distinguish this form of encephalitis from encephalitis lethargica, and to associate it rather with the form sometimes seen in measles, smallpox, and antirabic paralysis. Striking examples of the almost complete suppression of smallpox by mass vaccination of the population have been reported in Egypt

and in Uruguay. Undulant fever, spread by milk and cattle, has appeared also in Scandinavian countries, its catches in the United States have confirmed its association with *Brucella abortus*. In Denmark the disease has been shown to be more prevalent than typhoid or paratyphoid fever. In Rumania it has been found that the connexion of cases of poliomyelitis could generally be traced, and that for the most part the contagion came from direct contact with those suffering from the disease. There is a tendency in some countries to regard milk as a possible source of infection. Rumania is also faced with a difficulty in the treatment of general paralysis by malaria therapy. It has been found that in certain districts where malaria is common some patients are refractory to inoculation. Interesting questions of immunity in paludism are raised by this observation. There was considerable discussion at the session of the permanent committee on the subject of pre-immunizing infants against tuberculosis by means of B. C. G. Professor Calmette was invited to attend the session, and the results obtained by him are recorded in the report. Attention is drawn to the considerable variations in different countries of the infant death rate from tuberculosis. The report of the permanent committee concludes with the mention of what are described as four entirely new questions which are to engage its attention. The first is the subject of acute rheumatism, and the steps to be taken to prevent heart affections. Secondly, the committee will consider what measures should be adopted as regards intoxication by methyl alcohol and its relatively frequent result—blindness. Thirdly, there is the hospital question and its evolution in two directions—namely, the American conception of establishments for all classes and even for minor maladies, and the Czechoslovakian development of diagnostic centres for a definite area, whether urban or rural. The fourth question to be discussed is the more rapid diminution of mortality in towns than in the country, a condition which is said to obtain even in Poland. The remedy contemplated is the development of institutions of social hygiene and preventive medicine analogous to those existing in towns.

ANNUAL REPORT OF THE MINISTRY OF HEALTH

THE ninth annual report of the Ministry of Health, which covers the year ending March 31st, has now appeared, it follows in most respects the form of earlier issues, and the report of the Chief Medical Officer is, as usual, being published separately. Last year, however, the main report included accounts by the general inspectors of the administration of Poor Law, this year it is proposed to publish them in a separate volume, together with a reprint of the relevant section from the report under review. This report falls into five main parts, four sections deal respectively with public health, local government and local finance, the administration of the Poor Law and the administration of national health insurance and contributory pensions. The fifth section is devoted to the affairs of the Welsh Board of Health. Under the heading of public health are treated such subjects as international health work, general health questions, sanitary administration, food inspection, infectious diseases, maternity and child welfare, welfare of the blind, housing and town planning. Much of the ground covered in these chapters has already been traversed in earlier publications which have been the subject of notices in the *Journal* from time to time, but the present report brings the material together in a convenient form. Reference will be found in the preface to the steps taken to secure a reduction in maternal mortality, and to the arrangements made in co-operation with the British Medical Association for instituting investigations of all maternal deaths and all cases of puerperal fever. An analysis of local financial statistics for the year 1925-26

shows that of the total amount of money received as rates by local authorities in England and Wales in this year, 20.3 per cent was expended on health services. Of this 3.6 per cent was expenditure on lunacy and mental deficiency, 1.3 per cent on maternity and child welfare work, tuberculosis treatment, and venereal diseases, the balance (15.4 per cent of the total) covered expenditure in such directions as sewers, disposal of refuse, water supply, baths, parks, cemeteries, isolation hospitals, vaccination, salaries of medical officers of health not allocated to specific services, and port sanitary services. Education, it may be added, absorbed 20.9 per cent of the total income from rates, highways and bridges 19.6 per cent, and poor relief 19.3 per cent. Regarding national health insurance, it is stated that the total cost of medical benefit for the insured population in England (about 13,500,000) in the financial year 1927-28 was approximately £8,055,000, of which about £5,999,000 was paid to insurance practitioners. A brief account is given of the action taken by the Ministry in cases of alleged excessive cost of prescribing brought to light by the survey undertaken in the year 1925-26 by the regional medical officers, and continued last year, and reference is also made to the revision of the disciplinary procedure affecting insurance practitioners. Much interesting detail regarding local government affairs and finance, and statistical matter relating to the administration of national health insurance, is given in the appendices to the report, which is published by H.M. Stationery Office at the price of 5s.

THE ETIOLOGY OF TRACHOMA

On October 22nd, 1927, Dr Hideyo Noguchi left New York for Accra on the Gold Coast of West Africa. Before his departure he had almost completed an investigation into the causes of trachoma, and the concluding observations have been made by his assistants. The work has now been published by the Rockefeller Institute for Medical Research as a supplement to the *Journal of Experimental Medicine*.¹ This report begins with a review of earlier investigations since the days of 1883, when Koch found a minute bacillus associated with Egyptian ophthalmia. This was later shown by Weeks of New York to be the excitant of an acute conjunctivitis—"Koch-Weeks conjunctivitis." Many other similar observations were doomed to a like fate. Animal experimental inoculations were unsatisfactory, though Hess and Romer in 1905 succeeded in transmitting a trachomatous disease to two baboons, the lesions were, however, less extensive than the human disease, and cleared up in two or three months without leaving scars. The new research was carried out on untreated cases of trachoma among students of the Albuquerque Indian School, a few cases were chosen of the advanced type, and each was studied in the most minute detail. Monkeys were inoculated directly by fresh material. Though the employment of particular kinds of culture media and the use of low-temperature incubation, not only have a number of common bacterial forms—cocci, bacilli, and sarcinae—been secured, but, in addition, two distinct varieties of peculiar Gram-negative motile bacilli, from four of the five cases studied. The two kinds of motile bacilli are readily distinguished, since one grows well at 37° C. as well as at lower temperatures on ordinary media, whilst the other requires media containing animal blood, and thrives best at temperatures from 15° to 30° C. The latter organism does not multiply when oxygen is completely excluded. It bears resemblance to *B. monocytogenes*, but differs from it in inability to grow on ordinary media at 37° C., in its non-pathogenicity for rabbits, and in serological reactions. Under unfavourable conditions

the bacillus assumes forms found in the group of corynebacteria, but differing from these in showing motility under particular growth conditions. Single polar flagella are carried by the bacilli, which do not seem to have been described before. For the reasons that follow, the organism has been named *Bacterium granulosis*. The investigation was elaborate. Every organism found and cultivated in each case investigated has been injected in pure culture and in heavy suspension into the conjunctival tissues of macacus monkeys and the chimpanzee. With one notable exception, the cultures produced only fleeting reactions or acute inflammation, which soon subsided. The exception is notable because the injection of the culture of the bacillus called *B. granulosis* induced a persistent granular conjunctivitis resembling closely, and apparently identical with, trachomatous granular conjunctivitis in man. When the disease was induced in one eye the other later became involved, or if the second was directly infected from the first the advance was more rapid. Histologically the conjunctival lesions correspond closely with those of human trachoma, and include the characteristic follicle and scar tissue formation. The experimental disease induced in the macacus with the pure culture of *B. granulosis* has been transferred by direct tissue passage to the chimpanzee, baboon, and other *Macacus rhesus* through at least four successive passages, the clinical and histological characters remained the same. The lesions were infective as early as 17 and as late as 204 days after the original inoculation. The organism was recovered from these tissues, and has been seen in both human and monkey tissues. The great difficulty of its recovery in culture and its demonstration in sections of tissues and in films is not necessarily an indication of its absence from the lesions. The methods employed to recover and find the organisms may not be the most suitable for the purpose. No other organism obtained from the human cases of trachoma produced in animals effects comparable with those induced by *B. granulosis*. In the absence, therefore, of indications to the contrary, it is considered that this organism is the inciting micro-organism of trachoma in man. There have been so many disappointments in the past over researches into the etiology of trachoma that anyone will be forgiven caution in accepting new discoveries without independent repetition, but on the facts given the case for this new discovery is strong. The clinical and histological drawings of the monkey trachoma appear identical with those of human disease. Moreover, the clinical course of the disease in the monkeys was watched by half a dozen American ophthalmologists of first-rate repute and experience.

DARNLEY'S SKULL

PROFESSOR KARL PEARSON has generally made the scope of *Biometrika* a wide one, much to the pleasure and profit of those of his readers who are not mathematical statisticians, but he seldom has travelled so far from those metaphorical dry bones as when he writes of the actual bones supposed to have formed part of the skeleton of Henry Stewart Lord Darnley. Volume xx B, Part I, of *Biometrika* is entirely devoted to a critical study of the skull and portraits of Lord Darnley and their bearing on the tragedy of Mary Queen of Scots. Most of this volume is taken up with a discussion of the unsolved and probably insoluble riddles which have already been the subject of numerous histories and biographies, and have aroused so much partisan feeling. Professor Pearson is an enthusiastic defender of the character and doings of Mary Stuart, while he is equally a severe critic of practically all the other public men of England and Scotland of that day, including in that term the remarkable woman who ruled England. His suggested explanation of the strange happenings which ended with the blowing up of Kirk-o'-Field and the finding of

¹ The Etiology of Trachoma. Supplement No. 2. *Journal of Experimental Medicine*, vol. xlviii, No. 2, August 1st, 1928. The Rockefeller Institute for Medical Research, U.S.A. (Pp. 55-31 plates. Price 2 dollars.)

Darnley's apparently uninjured body in a neighbouring field is ingenious, although it needs a good deal more evidence than has yet come to light to substantiate it. It is perhaps a pity that this part of the study should not have appeared in a periodical of wider circulation and lower price, where it would no doubt successfully fan the always smouldering embers of Mary Stuart controversy into a temporary blaze. In a costly "journal for the statistical study of biological problems" Professor Pearson cannot find so large a public as his efforts deserve. Sir Arthur Keith, in the interesting and masterly study of the skull of Lord Darnley which appears on page 456 of this issue, confines his attention to anatomical and pathological considerations, only including such history as concerns the skull and thigh bone now in the museum of the Royal College of Surgeons of England. This article shows—as does all its author has written—great scientific acumen and a judgement that will not allow him to make or support any statement without sufficient evidence. As will be seen, Sir Arthur Keith very cautiously approves the opinions recorded by Professor Karl Pearson, while giving full weight to opposing considerations and quoting the adverse opinions of others. The verdict thus arrived at restores to royal honours and pathological importance two osteological specimens which have long been considered as impostors, and one of which, as mere "bric à brac," shared a drawer in the museum of the Royal College of Surgeons with a number of mere plebeian thigh bones. But while he thus restates these bones in historical importance, he also supports Professor Pearson in his assault on the character of Darnley—such as it may have been—for contumace. Yet the evidence is puzzling and somewhat contradictory. Despite the researches of Professor Pearson and the careful examination of the bones made by Sir Arthur Keith, it is still not certain that they are parts of the skeleton of that Henry Stewart, Lord Darnley, who was masterfully murdered at Kirk-o'-Field. If the bones are genuine it is still doubtful whether the pits and other appearances of the skull are due to syphilis. Sir Arthur Keith with commendable caution, declines to commit himself fully to an endorsement of Professor Pearson's conclusions, although he provisionally approves them. Until the four questions propounded in the last paragraph of the article are satisfactorily answered we think that we must concur in a verdict of "Not proven" on this as on some other happenings in the career of Mary Stuart. This caution is further justified when we reflect that twenty years ago some distinguished French savants discovered what they considered to be evidence of syphilitic bone disease in certain Nubian skulls, and that Professor Elliot Smith showed that these erosions and perforations were the work of beetles.¹

PETTENKOFER AND HIS WORK

Max von Pettenkofer,² by Major Hume of the Medical Corps of the United States Army, does not pretend to be in any way a complete biography, it gives a brief account of Pettenkofer's life, with an outline of his many and varied activities, but is mainly devoted to a review of his theories on cholera and other intestinal diseases. Born in 1818, Pettenkofer was taken in charge at an early age by his uncle, a chemist in Munich. In his uncle's society he probably developed that interest in chemistry which remained dominant throughout his life. After a varied career he took, in 1843, a medical degree at Munich, where he became professor of medical chemistry four years later. His general interests remained wide, as is shown by his

work on picture preservation. In 1865, at his request, a chair of hygiene was founded in the University, and he was appointed the first professor. Epidemiology gradually claimed his attention, but not to the exclusion of other health problems. He was always anxious to improve the conditions in his own city, and his efforts were ultimately attended with success, Munich being converted into one of the healthiest cities in Europe. After receiving many honours, he died by his own hand in 1901, leaving behind him a notable record of achievements in many fields. Pettenkofer's theories on the causation of cholera have not stood the test of time. While he recognized the existence of a specific germ, he held that it alone could not cause the disease unless certain local, seasonal, and individual conditions were favourable. His investigations were chiefly concerned with the first and second of these, and he maintained that the organism as it left the body was not infective until it had undergone ripening in a suitable soil. Major Hume gives a detailed account of Pettenkofer's work on cholera, and contrasts his views with those of Koch. In conclusion, he points out that while Pettenkofer's work on epidemiology was not confirmed by later workers, it was of the greatest value in stimulating contemporary research. As a chemist and physiologist he ranks with the great men of science, and many of his methods are in use to-day.

THE MEDICAL REGISTER UNTRACEABLE PRACTITIONERS

We publish in the *Supplement* this week (p. 129), at the request of the Registrar of the General Medical Council, a list of the names of those medical practitioners who have not replied to his inquiries as to the accuracy of their postal addresses. Any practitioner whose name is included in this list should communicate at once with the Registrar of the General Medical Council, or, in certain cases, with the Registrar of the Scottish Branch Council, at the addresses given on page 129.

By an Order of the Committee of the Privy Council Professor Robert Muir, M.D., F.R.S., Sir John Herbert Parsons, F.R.S., F.R.C.S., and the Right Hon. Sir Charles Philips Trevelyan, Bt., M.P., have been appointed members of the Medical Research Council, filling the vacancies caused by the retirement of Professor Georges Dreyer, Sir Archibald Garrod, and the Right Hon. William Graham, M.P. The new appointments become effective on October 1st.

DR. OLIN WEST, who is secretary of the American Medical Association, has been asked by the House of Delegates of that association, in session in Minneapolis at the annual meeting last June, to transmit to the medical profession in Great Britain an expression of the profound sympathy of American physicians in the loss of Dr. Adrian Stokes and Dr. William Young, who sacrificed their lives for the sake of the advancement of medical science. It is also stated that these names will be added to the list of those heroes of medicine whose memories are truly revered by the organized medical profession of the United States.

THE usual half-yearly indexes to the *Journal* and to the *Supplement* and *Epitome* have been printed, they will however, not be issued with all copies of the *Journal*, but only to those readers who ask for them. Any member or subscriber who desires to have one or all of the indexes can obtain what he wants post free by sending a postcard notifying his desire to the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W.C.1. Those wishing to receive the indexes regularly as published should intimate this desire.

THE SKULL OF LORD DARNLEY *

BY

SIR ARTHUR KEITH, M D, F R C S, F R S,
CONSERVATOR OF THE MUSEUM AND HUNTERIAN PROFESSOR, ROYAL
COLLEGE OF SURGEONS OF ENGLAND

THE historian in search of light on the most poignant, hot-blooded, and human of all tragedies recorded in history is not likely to consult the pages of the leading biometrical journal of our time, and yet I am convinced that in those pages Professor Karl Pearson records facts which give us a clue to the behaviour of that embodiment of tragedy Mary Queen of Scots, in the very crisis of her drama. The secret he has to reveal is of a medical nature, for medical secrets have often a more important bearing on the events of national life than orthodox historians have realized. Incidentally, too, Professor Pearson illustrates the part which craniology may play as the handmaid of biography.

Let me first tell the story of the skull and thigh-bone which Professor Pearson attributes to Lord Darnley, father of James I and grandson of Margaret Tudor, sister of King Henry VIII. The skull and thigh-bone are in the Museum of the Royal College of Surgeons, England, and my predecessor, Sir William Flower, described them in the catalogue thus:

No 345-345¹ *A remarkably depressed or tapeinocephalic cranium, and a femur, supposed to belong to the same individual, a male*

'These were purchased by the donor at the sale by Messrs Sotheby and Co, on March 22nd, 1865, of a collection of Fossils and Minerals, etc., formed during last [i.e., 18th] century by the Hon Archibald Fraser of Lovat, and described in the catalogue [of the sale] as skull and thigh bone of Lord Darnley

The internal evidence afforded by both bones conclusively negatives their authenticity. Darnley, at the time of his death in 1567 was about 22 years old and the bones are those of a man considerably more advanced in life and of great muscular development. The almost complete absence of frontal elevation, which is one of the most striking features in the skull, finds no corroboration in any of the known portraits and descriptions of the young Earl, and the femur could not be that of a person invariably described as tall or long, as, calculating at the usual ratio of 27.5 to 100, it would give a height of only 5 feet 2.2 inches.

"Presented by J. W. Belt Esq., 1869

No 745 *A left femur resembling the previous cranium in character and inscribed "Thigh bone of Lord Darnley, husband of Mary Queen of Scots, murdered and blown up Feb 10th 1567"*

Said to have been purchased with the above inscription at a sale at Sotheby and Wilkinson's with two other bones, 'Thigh bone of Little John, Robin Hood's companion, and shin bone of Humphrey Duke of Gloster,' by Mr F. M. Grimshaw (25, Gt Ormond Street, Bloomsbury) from whom this femur was purchased July 1st, 1880. It is that of a very tall man, and is probably the real thigh bone belonging to the cranium (345), 345¹ having been accidentally substituted. Length 5.58 mm.

In the light of subsequent events it is most probable that Mr Grimshaw sold "Little John's" femur to Mr Belt as that of Lord Darnley and later sold the real femur to our museum.

With such a verdict passed on them by my predecessor, the Darnley bones sank to the rank of bric-a-brac, and in that class they would have remained had not Professor Pearson come to their rescue. In recent years he has issued monographs "on skulls and portraits" of three famous men of Sir Thomas Browne, prepared by Miss Miriam Tildesley, of King Robert the Bruce, and of George Buchanan, prepared by himself. It was probably during his search in Edinburgh for documents relating to the Scottish historian George Buchanan that Professor Pearson came across the tracks of Darnley's skull. He found that in 1793 a skull reputed to be that of Lord Darnley had been "preserved among the curiosities of the

Antiquarian Society of Scotland," and that it exhibited "a melancholy proof of the effects of his [Lord Darnley's] incontinence." Professor Pearson found, further, that when the secretary of the society, James Cumming, "a most ardent collector," died in 1793, some items of the collection were sold along with Cumming's effects, among them the reputed Darnley skull. The same skull, with the "melancholy marks of incontinence," passed into the possession of the Hon Archibald Fraser of Lovat (1736-1815), whose collection was sold at Sotheby's on Thursday, March 22nd, 1865. The catalogue of the sale, it appears, is preserved in the British Museum, on consulting it Professor Pearson found:

'Lot No 164 Skull and thigh bone of Lord Darnley and cast from life of Oliver Cromwell preserved in the family of Noel.'

The lot passed to "Grimshaw" for the sum of six shillings, royal skulls went cheaply in 1865. There is no doubt that the skull and thigh-bone bought by Mr F. M. Grimshaw at the Lovat sale in 1865 are now the specimens numbered 345 and 345¹ in the museum of the Royal College of Surgeons.

Having traced the Darnley bones from Edinburgh to London, Professor Pearson turned his attention to their earlier history. Kirk-o'-Field was blown up on the night of February 10th, 1567, Darnley's body was found next morning in a neighbouring field or garden, with no outward injury, and had apparently been removed from his lodgings before they were blown up. His body was embalmed by the Queen's apothecary—for which he was paid £40—enclosed in a leaden casket, and on February 14th placed in the royal vaults of the Abbey Church of Holyrood. There it still was when the roof of the church collapsed in 1768. Later the royal vault became exposed, and somewhere between 1776 and 1778 Darnley's skull was stolen, later one or both of his thigh bones were removed from his coffin. All we know is that these parts became missing, and that in 1793 a skull reputed to be that of Lord Darnley was in the possession of James Cumming, an "ardent collector," and a thigh bone said to be Lord Darnley's was then, or soon after, the property of a collector of curiosities—the Hon Archibald Fraser.

Having read Professor Pearson's history of the Darnley bones, I turned again to their examination to see if I could obtain corroboration of his belief in their authenticity. The bones are of a brown tan colour—the colour which is given by burial in peat or in soil containing much vegetable matter. Always in such burials one finds the deep crevices and recesses of the bones—such as the depths of the ear passages and nasal cavities—packed with soil or earthy matter. On looking into the tympanum of the Darnley skull I found the ear bones in place and not a trace of soil, only the weathered tissues. On the deeper and unrubbed surfaces of the cranial bones, as on the femur, there clings a fine film of dry brown material such as is never found on bones which have been buried in the ordinary way, the appearances seen can be accounted for only by accepting such a history as Professor Pearson postulates for Darnley's bones. Further, I have no doubt the skull and thigh-bones are parts of the same individual, there is a community in their texture and state of preservation which bears out this inference.

But what of the indications of age? Lord Darnley was two years younger than Mary Queen of Scots, he was in his nineteenth year when he married her, being then a tall lanky lad, with a countenance which has been described as effeminate. In February, 1567, when he was murdered, he was in his twenty-second year. Are the bones those of a young man of 22? We have seen that my predecessor regarded them as those of an older person. Professor Pearson scarcely touches on this important point. Dr H. A. Harris, our leading authority on this matter, informs me that the lower growth line of the femur should be obliterated before the age of 22, and in Darnley's femur this line is not traceable except at one point. We can get no help in determining age from the teeth, they have fallen or been knocked from their sockets, but the sockets are free from disease and consonant with youth. The other source of information is the state of the sutures of the skull. The growth sutures of the base are closed, as

they always are before the age of 22. All the other sutures are open save one—the sagittal, which passes along the vault and separates right and left parietal bones. It is abnormally short, and has become, throughout the greater part of its course, prematurely obliterated. Strangely enough, this, the most outstanding feature of the Darnley skull, has escaped Professor Pearson's attention. This abnormality of growth is, as we shall see, the key to the chief peculiarities of Darnley's skull. The state of the sutures of the skull and of the lower femoral epiphysis is in keeping with Darnley's known age, and supports Professor Pearson's claim for authenticity.*

Readers of Professor Pearson's monograph will be struck by the pains he has taken to prove that at no time was it possible for the roots of trees or plants to reach the contents of the royal vault at Holyrood. I fear I am the cause of this particular part of his inquiry. One aspect—the right—of the Darnley skull has scattered over it a series of punched-like pits of various sizes, which I remarked when Professor Pearson began his inquiries, as areas which had been eroded by the action of spreading roots. I had compared the skull with others in the museum which were pitted by syphilitic gummatas, and found none to show identical lesions, nor did I find skulls which were known to have been eroded and marked by root action show pits of exactly the same form and character. That a wild and dissolute youth who had grown up in the courts of France and England may have contracted syphilis is probable, historians have suspected that he was a victim. Professor Pearson has reviewed the evidence of his illnesses and is convinced that when Darnley, a youth of 19, left England in the spring of 1565, to woo the Scottish Queen, he had already contracted syphilis, and when he was dallying with the Queen in Stirling Castle the secondary symptoms were upon him. By the end of the following year (1566) the disease, in Professor Pearson's opinion, had made such outward progress that Darnley did not dare to appear at the baptism of his son, who became James I, "because he was unrepresentable." Less than three months later Darnley was murdered.

Professor Pearson holds that the skull now in the Museum of the Royal College of Surgeons is truly that of Darnley, and that its pittings are the result of syphilis which at the time of his death had entered its tertiary or gummatous stage. It is unusual to find syphilis running so rapid a course in these later times, but the course of the disease was probably more precipitate in the middle of the sixteenth century. If Professor Pearson is right that from the days of his courtship until that of his death Darnley was riddled with syphilis and displayed on his body all its loathsome manifestations, then we can understand Mary's feeling of repulsion towards him and take a somewhat more lenient view of her wayward, light, almost criminal conduct at this period of her career.

But is the pitting of the skull really syphilitic? I had given my opinion that it was not, but in the light of Professor Pearson's discoveries I have re-examined all the pits. None of them shows the slightest trace of any inflammatory reaction of the bone in their walls or vicinity, some appear almost as if they had been "punched" out. But at the bottom of most of them is a brown scab, a root which erodes a hole in bone leaves no scab behind such as this. On the other hand, the pits are distributed almost entirely over the right aspect of the skull—the aspect which I supposed had looked upwards in the grave and had presented itself to the down-growing roots, the left aspect, which I had supposed to be the lower, was almost unaffected †.

* Since the above was written Dr. H. A. Harris has made a searching radiographic examination of both skull and femur. His observations lead him to conclude that appearances indicate a man over 25 rather than under that age. Professor T. Wingate Todd, our leading authority on age changes, also thinks that the state of the bones indicates an age over 22 years. While influenced by these weighty opinions I still believe that further observation will prove that the bones could reach the state here shown at the age of 22.

† Both Professor Todd and Dr. Harris regard the pits as produced by some artificial but unknown means long after death. Dr. Harris noted that both skull and femur had been coated by shellac and that the brown matter contained no haematin.

To settle this important matter, and being also mindful of Huxley's dictum that an unbisected skull is a disgrace to a museum, I caused the Darnley skull to be laid open, to see if there was any mark of syphilis within. There was no such indication, but there was the most definite evidence that the skull had rested on its left side, for in that half was the dried up rim of a pool of that same brown gummatous matter which had stained the open interstices of skull and femur. The condition thus revealed supports Professor Pearson's history of the Darnley skull. Further, on examining the cut surfaces of the tabular bones I found a few small cavities in the diploe lined by a thick brown material, roots could not have caused them, I know of no disease which could occasion such cavities except syphilis. So in this matter, too, I was driven to accept Professor Pearson's diagnosis of syphilis and give up my own of root action.

For a youth who stood six foot in his shoes the Darnley skull has a small brain cavity. Professor Pearson's measurement makes it 1,336 c.c.m.—about 150 c.c.m. under English mediocrity. The "kenskello" feature of the skull, however, is its broad, very low, retreating forehead—such a forehead as cannot escape observation and remark in life. Professor Pearson notes the abnormal shortness of the sagittal suture, but leaves its premature obliteration undiscussed. Nor has he called attention to another very remarkable feature—the outward bulge of the squamous parts of the temporal bone. Yet the low, retreating forehead, the small distance which the vault of the skull rises above the ear passages, the short fused sagittal suture, the bulging sides of the skull, all result from the same cause—a breakdown in the normal expansion of the skull to accommodate the growing brain. In this expansion, growth of bone within and along the sagittal suture takes a considerable, if undetermined, share. Failure of sagittal growth demands increased expansion at other sites of growth. The diag backwards of the frontal and the outward bulge of the temporals are attempts to compensate for sagittal failure.

An examination of the interior and cut surfaces of the bisected skull leaves no doubt that the characteristics of the Darnley skull are the result of an inherited anomalous mode of cranial development. Professor Pearson is inclined to be unduly liberal in the application of ugly epithets to Darnley's skull, but for my part it is just those cranial characters, of which Darnley was apparently the victim, which deserve our consideration. Darnley appears to have inherited this anomaly from his father, the Earl of Lennox, and to have handed it on to his son, James I. This uncommon disorder of cranial growth we may name the Darnley anomaly, for I have seen other instances of it, and it has all the appearances of a character which may be transmitted in a Mendelian way.*

Does the skull attributed to Darnley correspond with known authentic portraits of the man? Professor Pearson has been at great pains to gain access to, and to reproduce, all the authentic portraits of Lord Darnley, husband of Mary Queen of Scots. Certainly the portraits of Lord Darnley as a lanky youth of 17, preserved in Holyrood and in Windsor Castle, represent just such a youth as we should expect to possess, when the age of 22 was reached, the femur which Professor Pearson attributes to him. But when we come to apply the outline of the skull to the face and head of the portraits we encounter a host of difficulties and contradictions. Most of the portraits are of boyhood, between boyhood and manhood the face undergoes great changes. The facial parts, the jaws, cheekbones and supraorbital ridges all the animal parts concerned in mastication parts which mature after puberty are strongly developed in the skull now attributed to Darnley. The portraits, especially the early ones, reveal a youth with rather an effeminate face. At all times artists have painted to please their sitters and the sitters' friends rather than to produce an anatomical likeness. An artist selects an attitude which pleases himself rather than serves the needs of the craniologist. In my opinion

Professor Holt examined the skulls of over 700 young children and found two in which the sagittal suture was completely obliterated and ten in which it was partially obliterated.

one has to strain a point to fit the Darnley skull into his known portraits. Yet the fact remains that the youthful Darnley face revealed by his portraits may have developed into the robust development preserved in the "Darnley" skull.

For my part I hold that, although Professor Pearson has not completely proved his case, he has rendered it highly probable that the skull and thigh-bone preserved in the museum of the Royal College of Surgeons did form part of that youth who played so prominent, proud, and somewhat ignominious a part in a most tumultuous crisis in the history of Scotland. I am indebted to the author of this monograph for demonstrating to all the world how craniology may be made to serve as a handmaid to history, for just as the knowledge of a home gives us a clue to the men and women who occupy it, the knowledge of a skull gives us an intimacy with the kind of brain which at one time had its home within it.

I have reviewed Professor Pearson's monograph at length because it is the result of long and serious inquiry and because it raises a number of important questions which I, as well as other medical men, should be in a position to answer. Is it possible for a femur and skull to have reached the stage of growth seen in the Darnley bones at the age of 22? The answer, in my opinion, is yes. Is it possible for syphilis in less than two years to pass from the secondary to the tertiary stages of its manifestation and to produce the form of lesion seen in the skull? Is it possible for a youth with effeminate features at the age of 17 to possess such a robust development of jaws as is seen in the skull at the age of 22? Is it possible that it may be a skull from another embalmed burial? When we have obtained evidence to settle all of these questions, or when others have obtained it for us, we shall be compelled to acknowledge that Professor Pearson has proved his contention.

BRITISH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE

ANNUAL MEETING IN GLASGOW

THE ninety-eighth annual meeting of the British Association for the Advancement of Science opened in Glasgow this week, this being the fifth time that the Association has visited that city. Last March a Royal charter of incorporation was granted to the Association. On Wednesday the incoming president, Sir William Bragg, delivered an address dealing with modern developments of the physical sciences and their relation to national problems. The scientific proceedings of the meeting are arranged in thirteen sections—namely, mathematical and physical sciences, chemistry, geology, zoology, geography, economic science and statistics, engineering, anthropology, physiology, psychology, botany, educational science, and agriculture. The variety of topics dealt with under these headings can be imagined, and the programme for the present meeting includes such contrasting subjects as the sources of tin in prehistoric Greece, the metabolism of iodine, the question of hours in industry, the land of the Tuaregs, insects and Empire trade, factors affecting cell growth, the scope of the Child Guidance Clinic, and the biological aspect of the decay of stone in buildings and monuments.

An important announcement was made to the General Committee of the Association with reference to Down House. It will be recalled that on September 10th, 1927 (p. 464), we referred to the welcome news that Mr. George Buxton Browne, F.R.C.S., had generously bought the estate, and established a fund for its upkeep, to permit future generations to visit Darwin's home. It is proposed that the house and grounds shall be used by the British Association for the benefit of science, and that certain of the rooms, in particular the old study in which the *Origin of Species* was written, should be furnished as when Darwin lived in them, so far as may be possible. For this

purpose the original documents of Darwin's works, and various articles of furniture, are being collected by Mr. Buxton Browne and others. The Hon. John Collier has painted replicas of the well-known portraits of Darwin and Huxley to hang on the walls.

The Glasgow meeting is to continue until September 12th, and we hope to publish some further reference to the proceedings in our next issue.

Presidential Address (Craftsmanship and Science)

In his presidential address Sir William Bragg dealt particularly with the relations between science and craftsmanship in this country. He defined craftsmanship as the skill which was exercised in the production of whatever was wanted for human welfare, the qualities of which it was composed, including knowledge of materials, imagination, technical skill, perseverance, love of work, and sympathy both with the use to be made of it and with user. Sir William remarked that love of good work and delight in successful accomplishment were among the most powerful motives activating mankind, and when satisfied were sources of real happiness. Of all the motives which sway the world these were among the purest and best. By a simple analogy he showed that a people lived on what it made or earned, and that its success depended on its craftsmanship. He illustrated his point by reference to the productions of the Greeks, the Romans, and Indian workmen, adding that the craftsmanship of a people was an expression of the best of its very self, its very life, and an index of its health. He traced the development from the simple workshop of the old single-handed craftsman to the vast complex factory of modern industry which had come about owing to the urgent desire of the individual to better himself and his neighbours. He then showed how the craftsmen had called scientific knowledge to their aid, and he uttered the warning that hindrance of the growth of science in any way impaired the growth of craftsmanship. For the purposes of industry it was therefore necessary that there should always be a certain number of laboratories, or parts of laboratories, where scientific research might not be hampered by immediate thoughts of possible applications. Recent scientific discoveries had given rise to such thriving industries as these which were concerned with dyes, explosives, fertilizers, rubber, and artificial silk. Elaborating his main contentions he referred to the general connexion between science and mass production in industry, and remarked that, while many were benefited by the results of mass production, yet, when its processes called for little intelligence in their working, it would be found in the end that people of little intelligence were taking charge, science was therefore both the builder and the destroyer in respect of mass production. If craftsmanship was to improve continually, fresh industries and further adaptations of old ones must be sought. Moreover, improved craftsmanship depended in large measure on the absorption and adaptation of scientific discovery, and there must be direct practical contact with the problems to be solved. Sir William spoke of the new class of worker who was engaged in research associations and industrial research laboratories, and emphasized the importance of these men keeping in close touch with employers and shop workers. Such research workers deserved all possible encouragement. As an example of the subtle problems raised by new discoveries, he cited the radiation theory of light, upon which were largely based the great advances of nineteenth century physics, within the last twenty or thirty years, however, a new field of optical research had been opened up, and had shown that light had the properties of a stream of very minute particles. Here were two conflicting views about the nature of light, both of which had to be accepted, each hypothesis was used by physicists on appropriate occasions, though no reconciliation of the contradiction was as yet possible. In his peroration Sir William Bragg added that to the student of science there came a message to put his whole heart into his work, believing that in some way which he could not fully comprehend it was all worth while, every straining to understand his surroundings was right and good, and led him to be of use to his fellow men.

Nova et Vetera.

THE MUSEUM DIARIES OF JOHN THOMAS QUEKETT

TRADITION at the Royal College of Surgeons of England maintains that the vacant space under the lecture theatre was used by John Quekett, who succeeded Sir Richard Owen as conservator in 1856, as his dissecting and demonstration room. The tradition has been strengthened by the fact that one of Quekett's lecture tickets, of date 1857, has been found below the flooring. The room, now lit by electric light, has lately become a fine annex to the library, but it remains a question how it could have been used by a microscopist of Quekett's calibre, unless, indeed, he preferred a dark room for his microscopes, which were illuminated by gas probably at all times.

John Thomas Quekett, who was the master histologist of his time, was born in 1815, he was educated at home by his father, master of Langport Grammar School, Somerset, and became a microscopist at the age of 16, when he gave a course of lectures on microscopic subjects, illustrating it with his own diagrams, and employing an instrument constructed, we are told, out of a roasting-jack, a parasol, and bits of brass from a marine store. After serving his apprenticeship to a Langport surgeon and to his brother Edwin, he received his medical training at King's College and the London Hospital, obtained the diploma of L.S.S. in 1840, and in March of that year became the second student in human and comparative anatomy at the Royal College of Surgeons, the first, William Crozier, having been appointed by the Council in 1839.

In the first volume of his diaries, at the top of page 1, is this entry: "Mr J. Quekett commenced his duties at the Royal College of Surgeons on the 17th of August, 1840, since which time he has been engaged as follows." A careful account of the examination of the hair of a large cat is recorded, and then is unrolled, in many closely written pages, the history of a famous man's work in the Hunterian Museum. William Clift's "Museum Diaries" cover a period of some thirty-one years (1811-42). They are amusing in parts and always careful, but for minuteness and geniality Quekett's official diaries entirely outdo them. They date from 1840 to 1848, and chiefly cover the period (1843 onwards) when Quekett was assistant conservator to Richard Owen, William Clift's son-in-law and successor.

It is probable that Owen was a difficult chief under whom to be employed. Early in Quekett's service at the Museum we find Owen disapproved of by the Museum Committee, which was not satisfied by the way he spent his time. Owen, taking a large view of his position, said he worked for the credit of the College. To young Mr. Quekett he said "Busy yourself with pathology," but the committee had previously told the student in anatomy to confine himself to his own subjects. Between the horns of a dilemma, Mr. Quekett laid the matter before Mr. Edmund Belfour, the secretary of the College, who decided that the committee, and not the conservator, must be obeyed. Owen doubtless left matters very much in his own hands. Early in 1840 Charles Darwin presented the skull of a flat-nosed ox to the Museum, but no mention of Darwin appeared in Quekett's manuscript, either then or later. Manifestly, Owen himself negotiated with the great naturalist.

The diary of Quekett's period of studentship is at first quite grave and confined to strictly scientific matters, but gradually, as student merged into assistant conservator, we find a lighter note, and towards the close of the six ample quarto volumes of MS. we are at times almost in Pepsian company. The volume of eighty years ago (1847) may be taken as typical of the book as a whole. On February 16th Quekett records "Attend Mr. Langstaff's sale and make purchases to the amount of £21", and, on the 18th, "busy in unpacking the purchased specimens and in helping Hulme to make a Catalogue of them", and, on the 20th, "Still assisting Hulme [student in anatomy] when not otherwise interrupted." On the 23rd he was still busy making a catalogue of the lots purchased, with the prices affixed.

The sale of George Langstaff's valuable collection of pathological and anatomical specimens had been a disaster. It had taken place in October, 1842, before the collector's death. He was one of the original Fellows of the Royal College of Surgeons, created on December 11th, 1843, he was a born collector, pleasant, sociable, ever ready to impart his information to others. He impressed his friends as a great man with a magnificent hobby, which might entail his ruin. For years, as surgeon to St. Giles's workhouse, he obtained material for what came to be known as Langstaff's Museum. He sank his fortune, amounting to many thousand pounds, in the collection, for which the purchase of alcohol involved considerable expense in a period before the use of methylated spirits became known. He still supported himself with the belief that present loss of income could be compensated for by the sale of his museum. He neglected his large practice, and in 1842 published a laborious catalogue descriptive of 2,380 preparations, it had been baulked down from ten bulky MS. volumes.

The sale took place after the publication of the book, and, to Langstaff's disappointment, much of the collection went for less than the cost of glass and spirit. He suspended the sale at Stevens's auction rooms and applied to the Council of the College, who consented to harbour the collection and to make certain purchases. The specimens were moved to the College, and were either badly shaken in transit or badly put up in the first instance. He prided himself on being his own museum man. Eventually the Museum Committee spent £365 15s. 6d. on 1,500 preparations—a poor price in view of the fact that they had lately bought 307 specimens from Luston at his own price, £450. Langstaff died a few years afterwards a disappointed man.

On March 17th Quekett was busily occupied in getting ready some minutes for a meeting relative to the erection of a monument to the memory of John Hunter, and the matter was afterwards taken up by Sir William Lawrence and the Council. On April 4th "Candidates for the Fellowship, four in number, operate and dissect. One is ordered to tie the external iliac artery. He cuts into the abdomen the first thing and asks me to hold up the guts." In elephant, a dolphin, a wombat, a wolf-fish, and part of a dodo from the Ashmolean Museum were dissected, and there was constant preparation for demonstrations, and every day a minute description of some twelve microscopic preparations for his great catalogue. Every day, too, he received and examined singular pathological specimens and reported on them to their senders, many of whom were surgeons of eminence. On June 28th, in the midst of his multifarious occupations, his brother Edwin, John Quekett, also a microscopist and Fellow of the Linnean Society, in whose house the Royal Microscopical Society was founded in 1839, lay dying of diphtheria. "I stayed up with Edwin," writes John Quekett, "all last night, and, he being much worse, I did not leave him until he died, which was at ten minutes to eight p.m., being perfectly collected and aware of his situation all the time except at intervals."

But science has to hurry on as usual, and two days later the conservator dispatched Hulme, John Pearson, and others to fetch back from the Surrey Zoological Gardens parts of the elephant which had just died there. They returned loaded with the kidneys, ovaries, and so forth, and Quekett set to work to inject them, reporting the results at length in his diary. At the end of the year his demonstrations had come to be so largely attended that he repeated his lecture twice a day. He shirked no labour. On February 23rd and 24th, 1848, it assumed Herculean proportions.

Busily engaged in preparing for my demonstration I use one of my new microscopes for the first time. It answered uncommonly well after I had put some bottle indian rubber to it. I show on this occasion Phosphate of Lime, Triple Phosphates, and Carbonate of Lime, and the action of Polarized light on the two last. After the demonstration I go with Hulme and see a specimen of the *Balaena Proops*? which was on show near the Hungerford Market.

24 Thursday. Soon after my arrival I receive orders from Mr. Owen to be in readiness at six o'clock to go to Hungerford Market to take the viscera out of a large whale. I dine with him and get all things ready. At six o'clock no messenger arrived, so Hulme, Arldge, Searson, and myself set off but found that it was not to be commenced until one in the morning. We spent lots of time

in finding the owner. At 1/2 past one we commenced and loft off between eight and nine—a most troublesome job—up in nurkies in oil. Get home at ten o'clock and after breakfast sleep for two hours. Then having washed dressed and partaken of luncheon I start down to the College again. I give directions about preparing the parts we brought home and about having more of Sir Wm Burnet's solution applied. We consumed in all three quart bottles full the decayed smell was certainly destroyed but that of the oil was certainly not much acted on.

The day following

"I find that the men had again been sent to the whale. I go down there and this time we get os hyoides part of the larynx another part of the heart and a variety of other things. I go into the public house and there I pay all the men."

On the 28th

"Occupied all day in cutting up and disposing of the portions of whale. We well wash and allow them to soak in water all the night."

An alligator from the Zoological Gardens had then to be dealt with. This and other pathological investigations took till March 4th, when we read

"Occupied in the lower work room in getting bottles and other things ready for a campaign of whale mounting."

Hard work upon the whale continued, together with hard work upon a variety of other subjects. This is not to say that the diary is only a record of toil. There are many engaging references to family matters, dinner parties, games of loo, evenings in the society of great men. Yet we feel that the famous histologist was fretting his energies to atoms. He died at the early age of 46 in 1861, having succeeded Owen as conservator in 1856, since that year his health had failed.

V G P

India.

The Pasteur Institute of India.

THE position of the Pasteur Institute of India Kasauli, has been the subject of a correspondence between the body responsible for the conduct of the Institute's affairs and the Government of India, from which it appears that the Institute has been suffering from the failure of the provincial administrations to give adequate financial support. It will be recalled that the central Government is responsible, in the medical sphere, only for the provision of research agencies and for the care of persons residing in areas directly under its control. The research activities of the Pasteur Institute are financed by the Indian Research Fund Association, which is supported mainly by grants from the Government of India. About the beginning of the current year a request was made by the Institute to the central Government for a non-recurrent grant of Rs 229,000 and an additional annual contribution of Rs 20,000 to meet the cost of certain additions and improvements. As an alternative it was proposed that the Institute should meet Rs 122,000 of the non-recurring expenditure by the sale of investments and that the Government should make a non-recurring grant of Rs 107,000, but should increase the annual grant asked by Rs 6,000 a year to make good the loss due to the sale of investments. In its reply the Government recalls that it already makes an annual payment of Rs 16,700 on account of the treatment of persons from areas directly under its control, and suggests that its contribution compares favourably with the assistance given by some of the provinces. It is realized by the Government, however, "that a matter of this nature cannot be settled merely on a basis of arithmetical proportion or with strict regard to the constitutional obligations of the central and provincial Governments," and that if the work of the Institute is to be continued in accordance with modern requirements the existing buildings and equipment must be improved. The Government of India therefore proposes to ask the Standing Finance Committee of the Assembly to agree to a grant to the Institute of Rs 114,500 towards the estimated non-recurring expenditure, and to increase the annual grant by Rs 10,000, provided that an equivalent amount can be raised from other sources. This offer was considered at a meeting of the association which controls the Institute, at Simla in July, when it was decided to accept it but to ask that the proviso making the grant contingent on other financial assistance should be removed, as it was felt un-

possible to secure an equal amount elsewhere. It was also decided to ask the Government of India to consider the possibility of addressing the local Governments regarding the association's appeal. The association accepted the director's recommendation that the work of rebuilding must be proceeded with at once, and set up a sub-committee to undertake the work of additions and alterations. A gift of Rs 12,000 was received from the Maharaja of Dholpur towards the expenditure to be incurred in the provision of electric light.

Malaria in the Lower Bengal Delta

Particular interest attaches to the results of a malaria survey of the neighbourhood of Calcutta made by officials of the Bengal Public Health Department in 1920-24 in view of the fact that the conclusions reached suggest that the generally accepted view on the topographical factors affecting the incidence of malaria is inapplicable to the Lower Bengal Delta. The inquiry was initiated in the post-war years, when an acute housing shortage in Calcutta led to a demand for the development of the suburbs of that city, its purpose was to recommend, in relation to the incidence of malaria, the most suitable line which any projected extension of the city might take. Apparently this question is no longer causing concern as housing difficulties have become less serious, but the results are none the less interesting. An area of about 300 square miles, and containing 280 villages, was surveyed very thoroughly. Data were collected for each village relating to the prevalence of anopheline mosquitos—the number and nature of possible breeding places, the percentage of those that bred anophelines, the species of anopheles present, and the relative proportion of the different species. To measure the extent of malarial infection present all available children in each village between 1 and 10 years old were examined for enlarged spleen, the percentage of children with enlarged spleen to the total examined being recorded as the spleen rate for the village. The area surveyed consists of low-lying flat ground of very ancient deltaic formation, penetrated in parts by tidal waters and traversed by a number of rivers and canals, it includes the Salt Water Lake, and also several areas which are flooded for six months in the year. It is characteristic of deltaic topography in that the river-bank tracts are elevated ground, while the inter-riverine zones are depressions, in the higher areas the villages are comparatively dry, the subsoil water level is low, and there are relatively few large-sized collections of water, while in the low lying areas there is much accumulation of water in and around the villages and the subsoil water level is very near the surface. These two typical conditions are sharply contrasted in the report of the survey prepared by Mr M O T Iyengar, entomologist to the Bengal Public Health Department, because his investigations have revealed a close relation between the topography and the incidence of malaria. The striking feature is, however, that in this region he has found the relatively healthy and only moderately malarial areas to be usually those which are low lying, these areas were situated on a very low level and were subject to flooding. The endemic and hyperendemic areas were on elevated ground. It is therefore contended that in a deltaic country such as Lower Bengal stagnation of water and malaria, contrary to popular opinion, are not closely associated. Dr C A Bentley, Director of Public Health in Bengal, who contributes a foreword, states that this peculiarity in the distribution of malaria has been observed by him in other parts of the Presidency. It is interesting to note that Mr Iyengar's report, which contains much valuable detail not touched upon in this review, concludes with the opinion that it would be more practicable to reduce the incidence of malaria in the elevated regions by simple antimosquito measures than to undertake the drainage of the low-lying malaria free regions.

Tuberculosis in Delhi

Following consideration of a report on the prevalence of tuberculosis in Delhi, submitted by Dr Sethna, medical officer of health, the municipality approached Major J R D Webb I M S, assistant director of health, with a request for advice and suggestions. Major Webb after

making a survey of the city, has prepared a report in which he emphasizes the need for relieving congestion. He believes that the solution of the problem of tuberculosis depends upon this factor, and, understanding that the formation of an improvement trust is impracticable, urges that strong representations should be made to the central Government for financial assistance to relieve congestion. The five years' programme of health and sanitary improvement recently formulated by the municipality is regarded as a step in the right direction. Major Webb suggests three means of providing some immediate relief from the problem under consideration: (1) tuberculosis dispensary work, (2) education of the public, (3) prevention of further congestion in the already congested areas of the city. While admitting the value of voluntary efforts, he doubts whether real success in anti-tuberculosis propaganda work can be achieved unless it is entrusted to a whole-time paid staff. Referring to the third point, he suggests the need for much stricter control than exists at present over building activities, and for rigid administration of the building by-laws. He compares the conditions existing in the congested areas of Delhi to-day with those in London over three hundred years ago at the time of the "great plague."

Grant Medical College, Bombay

The report of the Grant Medical College, Bombay, for the year 1927-28 records several notable improvements in its position and equipment. It has been regarded in recent years as a reproach to the college that it was overcrowded, but in this respect matters are now much better, the number of regular students, which was about 1,150 in the years 1921-24, had fallen to 518 in 1927 and to 418 this year. At the same time steady progress has been made in organization and equipment, and work on several important extensions is now proceeding. In January operations were commenced in the construction of a new building to accommodate the pathological museum and the bacteriological and clinical laboratories, with ample facilities for post-graduate instruction and research. This addition has been made possible by a donation from Sir Darab Tata of approximately half the cost. It is proposed, with the new quarters available, to reorganize the departments of pathology and bacteriology so as to correlate and extend instruction in these subjects. The new dental school and hospital which is under construction will, it is claimed, be the only institution of its kind in India. Extensions to existing hospitals and the establishment of new ones will shortly add considerably to the facilities for clinical instruction. The report was read at the annual prize distribution on March 8th by the dean of the college, Captain S. L. Bhatia, M.C., I.M.S. Sir Leslie Orme Wilson, Governor of Bombay, who presided, referred to the progress of the institution, and went on to speak of the change which had followed on the progressive reduction in the strength of the permanent Government medical services, to which was due so much credit for building up the system of medical education in India. These officers, he said, had largely been replaced by independent members of the medical profession, and it was a matter for satisfaction to see such a large number of Indian professors carrying on the same traditions in responsible appointments in the college. The appointment of associate professors, who were the pick of the profession in the city, and the appointment of short-term house-physicians and house-surgeons showed that they were endeavouring to readjust, as he thought they should, the hospital and teaching staff on the lines followed by the large hospitals in the United Kingdom.

We are indebted to Captain Bhatia for the following information regarding the early history of the college, which is among the oldest medical schools in India. It owes its existence to Sir Robert Grant, then Governor of Bombay, who was responsible for the institution of an inquiry by the Medical and Physical Society of Bombay (which he had founded) into the desirability of establishing a medical school. Receiving a favourable opinion from this body, Grant, in 1838, addressed a memorial to the Court of Directors of the East India Company at Calcutta—then the capital of British India. The scheme was sanctioned, but before the news was received in Bombay its author had died. His name is perpetuated in that of the college,

which was opened in 1845, the cost being met half by public subscription and half by a contribution from the East India Company. A teaching hospital was also provided, the necessary funds being supplied largely by Sir James John Teesdale, whose name it bears. It is interesting to note that there had existed in Bombay at an earlier date the first medical school in India, but after six years of existence it proved unsatisfactory and was abolished. The Bengal Medical College at Calcutta was opened in 1835.

Women's Medical Service Difficulties

The development of medical services for women in India is being hampered by the lack of funds and the lack of interest on the part of the provincial Governments within the spheres of which this work falls. An effort to secure additional assistance from the central Government for the development of the Women's Medical Service has proved unsuccessful. In the report of the National Association for Supplying Medical Aid by Women to the Women of India (which incorporates the Countess of Dufferin's Fund and the Women's Medical Service) for 1927, it is stated that the present subsidy from the Government of India will, at present rates and with the present very low average of service (about eight years), only pay for a cadre of forty-two doctors. With the rapid Indianization of the Women's Medical Service a longer average service is to be expected, involving greater expense in pay and allowances. The reduction of the cadre from forty-four to forty-two means the elimination of two sanctioned posts, and it has recently been necessary to refuse two requests for officers for new posts. An application was made last year for an increase in the subsidy from Rs 3,70,000 to Rs 5,00,000, to provide for eight more officers, it was proposed to employ several of these for special maternity and child welfare posts, one, at least, being available for research work into the causes of antenatal and infantile mortality. The Government of India, however, replied that it had decided not to concern itself further with the pay or strength of the Women's Medical Service, pointing out that medical administration was a transferred subject of administration in governors' provinces, and suggesting an appeal to the local Governments or to the general public. A request has therefore been addressed to the provincial authorities concerned asking them to contribute towards the salaries of W.M.S. officers employed in Dufferin Hospitals. An application has also been made to the Rockefeller Foundation for a grant for research work. The Dufferin Fund has continued to aid hospitals exclusively for women and children by supplying W.M.S. officers, free of cost, to take medical charge and by giving grants-in-aid to the limit of its income. The apathy of the provinces has made the work difficult, the local Governments do not yet accept responsibility for medical aid to women and children in the way and to the extent that they do for men. The Central Provinces, however, are mentioned as a notable exception, here medical aid to women has made rapid strides, and several new hospitals have been provided.

Mentally Defective Children in India

Attention is called to the absence of any institution in India for the care of mentally defective European children in the report for the triennium 1924-26 of Lieut.-Colonel Owen A. R. Berkeley-Hill, I.M.S., medical superintendent of the European Mental Hospital at Ranchi, which receives European and American patients from all provinces in Northern India. Colonel Berkeley-Hill states that in 1926 three mentally defective children were admitted to the hospital, which is not regarded as a suitable place for their treatment. He accordingly submitted to the board of trustees a proposal to provide, as an experiment, an annex entirely outside the hospital enclosure for the accommodation of twenty children, mentally defective, but not certifiable under the existing Lunacy Act. The question of principle involved has been referred to the local Government for consideration, since this type of institution has never existed in India, and legislation to authorize the State to assume charge of such children would be necessary. According to the superintendent of the St. Andrew's Colonial Homes, Kalampong, the studies carried out in the homes have shown that nearly 5½ per cent of those resident

there were mentally defective. The report states that this figure indicates the gravity of the question, for this class of children has a grave bearing on all sociological and economic problems, but more particularly those of vice, crime, and pauperism. Colonel Beikley-Hill considers that, while a few institutions of the type recommended would not deal effectively with the problem, they would serve a most useful purpose in educating public opinion and arousing interest in it. In the Madras Presidency, it may be added, the establishment of a home for mentally defective children is under consideration.

Union of South Africa.

Jubilee of the Royal Society of South Africa.

On August 1st a very successful *conversazione* was held in the Hiddingh Hall of the University of Capetown to celebrate the jubilee of the Royal Society of South Africa and the inauguration of the Medical Association of South Africa (British Medical Association). The large number of representative guests, including many notable figures in the scientific world of Capetown, were received by Mr T Lindsay Sandes (president of the Cape Western Branch of the Medical Association) and Mrs Sandes, and by Professor W A Jolly (president of the Royal Society of South Africa) and Mrs Jolly. Professor Jolly, who is a past-president of the Cape Western Branch of the Medical Association and at the present time one of its vice-presidents, gave a short but concise account of the activities of the Royal Society since its inception in 1877, under the name of the South African Philosophical Society. Mr Sandes depicted similarly the growth of the British Medical Association from its birth up to the present time. A musical programme and a dramatic reading were followed by the presentation of a British drama in the Russian manner, entitled "Love Lies Bleeding," staged by the Play Reading Circle of the University of Capetown.

Mental Deficiency

On May 10th, when the Lower House in Committee of Supply discussed the estimates of the Department of the Interior, the necessity for dealing with the Union's increasing number of mental defectives came in for serious consideration. The subject arose in connexion with immigration. An Opposition member drew the attention of the Government to the importance of the problems to be considered in determining the character of the future population. It was pointed out that international conferences on immigration held largely in Europe and sometimes under the aegis of the League of Nations were rather overbalanced by emigrant-exporting countries, which were most concerned with keeping an open door for the less desirable inhabitants of the overcrowded territories. South Africa's aim should be to build up a nation of citizens of a type best qualified to maintain white civilization in that part of the world. Another Opposition member thought that the time had arrived when the immigration laws should provide not only for the exclusion of undesirables, but for the introduction of people of a type suitable to the conditions of the country. The chief ingredients of the European population were of northern stock, and they should introduce people more likely to assimilate with the existing stock than was at present being done. They wanted producers who would make their homes in the waste spaces rather than the present stream of unproductive small traders. Following naturally on a discussion of the need for preventing the deterioration of the European stock in South Africa by the immigration of undesirables, came a debate on methods of dealing with mental defectives. Mr Alexander (Constitutional Democrat) considered that the rate at which the mentally deficient population was increasing was becoming a very serious problem. There ought to be no difficulty in South Africa in legislating against the marriage of persons declared mentally deficient, a better procedure was sterilization, about which advanced views were held in some other countries. The Rev Dr van der Merwe,

declared that the Government had never yet tackled in a practical manner the problem of dealing with mentally deficient children. At least 1 per cent of the school-going children of the Union fell within that category. Special provision should be made for such children. Their educative laws demanded that all children between certain ages must go to school, but such abnormal children were exempt, and they often grew up without any sort of training whatever, least of all that sort of education which would keep them out of the criminal ranks. He estimated the number of such children in the Union at 3,500. The Minister should make an early start in the provision of education by appointing specially trained men to look after such children. The Minister for Public Health said that a great deal of work was necessary on behalf of the normal children of the country before the Government could think of spending more money on abnormal children. The definitely deficient child (in contrast with the "backward child") fell under the Mental Disorders Act, and was sufficiently provided for by two institutions. Intelligence testing was being done gratis by university professors. A grant of £4,000 had been made by the Carnegie Trust to investigate the "poor white" problem, including the relationship between mental deficiency and poverty.

Medical Golf

Present-day interest in the rural and ancient game is reflected in the activity of the golf section of the Cape Western Branch of the Medical Association of South Africa (British Medical Association), which has now a membership of between thirty and forty. An attractive programme has been arranged for the current year, including matches against the dental surgeons, the united banks, the journalists, the insurance companies, the ladies, the university, the Bar, and the navy. Matches are played usually on the third Wednesday of each month on the various courses of the peninsula. The annual competition for the Jones-Phillipson cup was held on July 11th over the course of the Royal Cape Golf Club at Wynberg, and resulted in a win for Dr C W Comrie-Shaap, the runner-up being Professor A W Falconer. The winner, whose first success it is in this competition is an ardent golfer, and is at present captain of the Metropolitan Golf Club. Much of the credit for the present enthusiasm of the medical golf section is due to Mr C E Jones-Phillipson, who, as honorary secretary, has done much to reawaken interest among medical golfers.

Scotland.

Aberdeen Royal Infirmary

THE PRINCE OF WALES, accompanied by his brother, the Duke of Gloucester, visited Aberdeen on August 28th for the purpose of laying the foundation stone of the new Aberdeen Royal Infirmary at Foresterhill. An address presented to the Prince stated that the history of the Aberdeen Royal Infirmary went back over a period of 200 years, and that the present building had served its generation well, but was no longer adequate to the needs of the times, as its situation was in a noisy and crowded area of the city. The cost of the new infirmary would be £400,000, and nearly the whole of this sum had already been raised by the freewill offerings of the people. The address continued that the new Royal Infirmary would be merely a part, although an essential and important part, of a large scheme which had as its ultimate object the concentration of the principal medical services of the city around one site. The originator of this scheme was Emeritus Professor Matthew Hay, for many years medical officer for the city. One of the chief advantages, it was pointed out, would be the concentration in the task of healing of the best and most experienced professional skill in the city of Aberdeen, thus giving a new impetus to the teaching work of the medical school. The Prince of Wales, before laying the foundation stone, expressed the conviction that the whole sum required would be speedily raised, and said that the joint hospital scheme appealed to the

imagination by the many advantages, such as economy in administration and equipment, which would be obtained when all the units were on one site.

Dunfermline Hospital Extension Scheme

His Royal Highness the Duke of York, accompanied by the Duchess, visited Dunfermline on August 11th, and laid the foundation stone of the new extension to the Dunfermline and West Fife Hospital. The freedom of the burgh was conferred upon the Duke and Duchess, who thereafter proceeded to the hospital for the opening ceremony. Mr H M Brownlie, chairman of the board of management, who presided, and who was accompanied by Dr Tuke, Dr Fleming, and Dr Cameron of the medical staff, said that more accommodation had been required in the hospital for many years, and contributions to the extension fund now amounted to over £31,000, so that the managers hoped that when the time arrived to open the extension it would be possible to say that it was free from debt. The Duke of York said that they were all compelled to keep a watchful eye on expenditure at the present time and were no longer, unhappily, able to indulge each and every generous impulse, but he was certain that the claims of a local hospital upon the community for whose benefit it existed were strong enough not to be ignored. He expressed the hope that the example of those who had already contributed would be followed by others, and that the Dunfermline and West Fife Hospital would have many years of useful service. The hospital was originally opened in August, 1884, with 16 beds and a staff consisting of a matron and two nurses. In less than six months 4 more beds had to be added. Notwithstanding frequent subsequent extensions, the shortage of accommodation continued, and in the summer of 1925 it was definitely decided to utilize the present site and adjoining properties for extension. The purchase price of Priory House and grounds, in the immediate neighbourhood, was presented by Mr James D Spence, and plans for the extension were prepared. These provide for two new wards, each of 21 beds, an additional operating theatre, an out-patient department with special out-patient operating theatre, a bacteriological department, new kitchen and laundry accommodation, and a new heating system. A department for electrical and orthopaedic treatment will also be provided, the equipment having already been promised, while the neighbouring Priory House will be refitted as a residence for nurses. The estimated cost of the extensions is £50,000.

Dundee Royal Asylum

The 108th annual report of the directors of the Dundee Royal Asylum, dealing with the year ending June, 1928, has been issued. The medical officer, Dr A B Dalgetty, draws attention to the fact that the past year was noteworthy as the first in the history of the asylum in which the number of voluntary admissions exceeded those admitted under certificate, the figures standing in the ratio of 70 to 20 per cent. Of 88 patients under treatment during the year, 14 were discharged and 7 died. Of those discharged 8 had recovered and 5 were relieved, while of the 7 patients who had died 4 were over 70 years of age. The financial statement of the institution showed an excess of income over expenditure of £968.

England and Wales.

The Royal Westminster Ophthalmic Hospital

The new Royal Westminster Ophthalmic Hospital, which has been under construction since November, 1926, was opened for the admission of in-patients on September 3rd. It replaces the old hospital in King William Street Strand where the work of the institution was carried on for ninety-five years out of the 116 years of its existence. Situated in Broad Street, Holborn, near New Oxford Street and Shaftesbury Avenue, where it is easily accessible from all parts of London, the new building is regarded as one of the finest of its kind in the United Kingdom. The out-patient and casualty departments, opened at

Easter occupy the whole of the ground floor, and provide facilities for treating 500 patients daily. Fourteen single private wards, which are intended to meet the needs of those who cannot afford the expense of private nursing home accommodation but are ineligible for the ordinary wards of the hospital, will be available in the autumn. The new building has been designed to furnish the rapid and prompt treatment so often necessary in eye diseases or accident. It has cost almost £100,000, exclusive of the freehold site, the total expenditure being about £150,000. Nearly two-thirds of this has been met by the response to a public appeal and from the proceeds of the sale of the old site. The hospital is recognized by the University of London as a place of study for the M.S. degree in ophthalmology. Instruction classes for the D.O.M.S. recommence next month in the fine new theatres and laboratories.

Cremation in England

The Cremation Society of England has issued a pamphlet, No. xxxiv of its *Transactions*, containing the report of the council for 1927, an account of the proceedings at the annual meeting last March, a review of the movement in Europe, and the papers on cremation read by Drs H T Herring and Preston King at a sessional meeting of the Royal Sanitary Institute at Bath in May, 1927. It appears from the report that during the last year 3,266 cremations were carried out in Great Britain, as compared with 2,877 in 1926, an increase of 13.52 per cent. A new crematorium has been erected at Bristol, while others are being provided in Ipswich, Nottingham, and Guernsey, the question of making such provision is receiving attention at Stoke-on-Trent, Blackpool, Edinburgh, Bournemouth, Southampton, Portsmouth, Brighton, and Islington. The Births and Deaths Registration Act, 1926, made necessary various amendments to the existing regulations, and it is stated in the report that the Home Secretary is revising the statutory rules and orders made under the Cremation Act. It is hoped that many of the serious disabilities which hitherto against cremation will be removed. Reference to this question was made in the *Journal* of April 23rd, 1927 (p. 770), when the view was expressed that the existing requirements "are very stringent, possibly even over-stringent if cremation is to be preferred and encouraged as a public health measure to replace burial." At the annual meeting a communication from Sir Thomas Hordey was read suggesting that for the more rapid extension of the practice of cremation they must perhaps look to the poorer classes of the community. Sir Thomas Hordey remarked that legal requirements added both to the expense and to the formality of this mode of burial, and that it ought to be possible to provide for effective certification in a modified form under the national health insurance scheme. It was obvious that if cremation followed only 10 per cent of the deaths in this country the cost could be reduced very much below that of the commonest form of burial. Professor A Bostock Hill, who presided at the opening of the meeting, emphasized the importance of educating the public, and commented on the desirability of a return to the old idea of the church and the churchyard being the centre of village life. At present many of the village churchyards were full and had been closed, while new cemeteries had to be opened at heavy cost. If they could give each community a crematorium, he suggested, then the people might return not to burial, but to the disposal of the remains of the dead in the churchyard. Another speaker quoted a letter, written by a representative of the Minister of Health, in which it was stated that the interment of an urn containing cremated remains was permissible in any churchyard in England and Wales which had been closed by Order in Council. The report states that in Germany, where 45,758 persons were cremated in 1927, there was no uniform law, each State prescribing its own requirements. The offices of the Cremation Society of England and of the Golders Green and Woking crematoriums, it may be added, have been removed to 23, Nottingham Place, London, W1. Life membership of the society is obtainable by payment of 5 guineas, or six consecutive annual subscriptions of 1 guinea. This provides for cremation at any British crematorium without fee.

After-Care of Mentally Defective Children in Birmingham

An interesting account of the present position of the ex-pupils of the Birmingham Special Schools for Mental Defectives is given in the report of the After-Care Subcommittee for 1927. Statistics have been compiled relating to 4,301 persons, some of whom are now over 40 years old and left school nearly thirty years ago. The total includes 2,501 males, of whom 1,108 were doing remunerative work, and 1,800 females, of whom 587 were doing equally well, the average wages of the males were 31s 3d per week, and of the females 20s 7d. In some cases, however, earnings were small, while others were considerably above the average. Of the remaining cases 280 have been excluded from special schools through mental or physical disability. 667 are living at home and doing no paid work (this includes a number of employable girls on household duties in their own homes), 178 have been transferred to ordinary schools, 587 are in institutions, and several have been lost sight of through removals. Inquiries are conducted from time to time into the family histories of ex-pupils of special schools who are known to have married. The most recent investigation covered 284 families, into which 514 children had been born in 165 cases the father, and in 119 cases the mother, had been certified as mentally deficient. Particulars relating to the sex of the children show, so far as they go, that with one parent mentally deficient relatively more infants of the other sex have been born. Most of the children are still too young to allow any accurate diagnosis to be made of their mentality, 344 being under the age of 5. Of the 170 children over 5, 115 are known to be attending ordinary elementary schools, while thirty-nine are 5 years old only, and the reports do not indicate what school, if any, they are attending. Five attend special schools for the mentally defective and one has been excluded from such a school, two are at a colony for defectives, three in other institutions, and five are at work. Among children under the age of 5 years, five are reported to be subnormal. It has been noted that the tendency is for the deficiency of the parent to emerge with more frequency in the children of the opposite sex.

Dairying Research at Reading

In the report for 1927 of the National Institute for Research in Dairying, which is associated with the University of Reading, attention is again called to the difficulty experienced in securing adequate funds. An application for assistance from the Empire Marketing Board was granted, but the Ministry of Agriculture has been unable to respond to a request for funds for capital expenditure or to hold out any hope of an increase in the annual grant for maintenance. It is added that if no way out of this latter difficulty can be found some of the research institutions which have been started will be seriously handicapped. Discussing the need for further developments of the work of the Institute, it is suggested that the first step necessary is the appointment of a physiologist to study the problems of milk secretion, continuing this work from the point to which it has been brought by the existing staff. Increased accommodation at the farm, extended laboratory facilities, and alterations to facilitate experiments with dairy appliances are also regarded as immediately necessary. Meantime much work in progress at the Institute is of direct importance to the dairying industry, investigations are being conducted of conditions necessary for the efficient use of a milking machine, and the study of the cause of "oily" milk. Experiments have also been made with a view to increasing the vitamin content of milk in winter, and in the effect of pasteurization upon milk infected with tubercle bacilli.

Harrow Mothers' Hostel

The report of the Harrow, Wealdstone, and District War Memorial Maternity Hostel for the year ended March 31st states that in the period under review there were 138 patients, the average weekly cost of each being £5 3s 11d or £5 12s 7d if allowance be made for repairs and renewals to the hostel. The average amount paid weekly by patients was £3 2s, 17 paid from 15s to £1 10s, and 29 from £5 to £5 5s a week, weekly payments

by the remainder ranging between these amounts. It should be noted that the 17 patients mentioned as paying small amounts were nominated by the urban district councils of Harrow and Wealdstone, each of which makes a grant to the hostel and has the right to nominate a certain number of cases at special fees. Owing to the increased number of local applicants for admission an agreement which gave the Middlesex County Council the right to nominate certain cases from other areas has been terminated. The need for extended accommodation has become still more apparent and, while the question of building has been deferred pending changes in the district boundaries, a suitable site has been secured and a reserve and development fund is being built up. In her report the visiting medical officer, Dr Frances Huxley, states that of the 138 patients confined during the year 113 were admitted from the ante-natal clinic, after regular attendance there, and 25 were under the care of their own doctors. Medical help was needed to aid delivery in seven cases, and for complications after delivery in eight other cases, three babies were stillborn, and two survived only a few hours after birth. Commenting on the increasing desire for admission to the hostel Dr Huxley remarks "It is not nearly large enough. Patients are beginning to apply so early for admission lest they should miss their chance, that I have sometimes difficulty in determining whether they are going to have a baby or not!"

Ireland.

Resignation of Dr E C Thompson

DR E C THOMPSON, who has been surgeon of Tyrone County Hospital, Omagh, for more than fifty-three years, has tendered his resignation following the death of his wife. The chairman of the Committee of Management of the Tyrone County Council on August 21st expressed sympathy with Dr Thompson in his bereavement, and paid an eloquent tribute to his work in the hospital. A resolution was carried recording the high appreciation of the council of Dr Thompson's long and faithful service, and his medical colleagues in Ulster have joined wholeheartedly in the tribute. Dr Thompson succeeded his father in this appointment, so that the post has been held by the family for ninety-five years. He was a familiar figure at local medical meetings, and was for many years vice-president of the Ulster Branch and chairman of the Tyrone Division, for the formation of which he was largely responsible. Before the establishment of the Free State he was well known in Dublin medical circles, and as a staunch champion of the privileges of the profession carries with him in his retirement the good wishes of its members in both Northern and Southern Ireland. He was a candidate for the Parliamentary representation of Tyrone on more than one occasion, and sat as a Constitutional Nationalist from 1899 to 1906, when he took an active part in advocating the necessity for proper housing accommodation.

Queen's Institute of District Nursing

Following the establishment of two governments for Northern and Southern Ireland, the question of the control of the Queen's Institute of District Nursing in Ireland gave rise for some time to considerable discussion. It has now been decided to form an independent executive committee for Northern Ireland in the belief that the area will thus be better served than if it remained under the council in Dublin. Under the new arrangement the North and the South will each have an autonomous executive committee, with its own trustees and its own training centre. It has, however, been decided by the London Council that, in the interests of nursing as a whole, it will be better to retain the Irish Council, on which the whole country will be represented in proportion to population. The duties of this All-Ireland Council will, it is stated, be purely formal, but the principle of unity in nursing, even if only in name, has been insisted on by the headquarters of the institute.

Hospital Provision in Wicklow

Dr Raverty, medical officer for Bray, has written to the Wicklow County Board of Health stating that a serious position as regards hospital accommodation is likely to arise in the near future, and urging that the matter be investigated at once. He said the establishment of a sanatorium at St Columbkille's for cases of pulmonary tuberculosis would be a menace to the lives and health of the people of the locality, and that the hospital arrangements proposed would be utterly unsuited to, and inadequate for, the requirements of the sick poor. A resolution was passed requesting the responsible Minister to take steps to see that the arrangements made for the treatment of the sick poor in St Columbkille's Hospital for Rathdown No 2 Area by that board with the former Rathdown Guardians are continued, or, if this is not feasible, to arrange for their treatment in their own area, since the cancelling of the original arrangements would seriously affect the poor of the district, and alterations could not be made without heavy expenditure being incurred.

Correspondence.

TONSILLECTOMY AND REMOVAL OF ADENOIDS

SIR.—The discussion on the selection of the anaesthetic for the removal of tonsils and adenoids tempts me to refer to the practice I adopted soon after the department for diseases of the throat was established at Guy's Hospital in 1884. Having removed adenoids as early as 1820, when chloroform was the only anaesthetic used for children, one found that not only was there anxiety, but the time occupied—especially in recovery—was incompatible with out-patient work. With the rapid increase in the number of cases, amounting in a few years to 300 per annum, it became necessary to devise a method of inducing anaesthesia which would fulfil four conditions: a minimum of risk, rapid induction of complete anaesthesia, its maintenance after cessation of inhalation during the deliberate removal of tonsils and adenoids, and the speedy recovery of the patient.

The late Matthew Corner of Poplar, who will be remembered as a wise and experienced general practitioner, as well as surgeon to the Poplar Hospital, called me to a case of hepatic abscess. Observing that he was about to administer ether, and, from my experience at Guy's, expecting the induction would take some time, I was leisurely preparing my instruments when, within five minutes, came his summons, "Ready." It was amazing. Mr Corner, who had used Clover's inhaler of a new and convenient pattern, gave me a few hints as to its use. I bought the apparatus next day, took it to the hospital, and perfected myself in its use until without fail I could obtain complete relaxation in children within five minutes, and in nearly all adults. One of my colleagues, Dr Lancaster, learned the method, and we combined in the out-patient department, with the result that four minutes sufficed for the induction, this gave four minutes' complete anaesthesia for the operation, and without total abolition of the throat reflex. This is time enough for anyone practised in the guillotine, and, moreover, allows for the separate curetting of Rosenmüller's fossa.

Taking the operations at Guy's over a period of twenty years and those in private a moderate estimate gives about 4,000 cases. There was no fatality and only one case of troublesome hæmorrhage, and that was a private case, a boy aged 8.

Recognizing the danger of chloroform, especially in the hands of the occasional administrator, I always took Clover's apparatus and a supply of ether to cases in private when the general practitioner was to be the administrator, and in this way introduced the method to many practitioners, the best of whom adopted it. With a little practice complete anaesthesia can be obtained for other short proceedings such as tooth extractions, rectal examinations, reduction of dislocations, etc.

Ethyl chloride, even given by special anaesthetists, did

not, in my experience, allow sufficient time for clearing Rosenmüller's fossa or for curvetting the remaining portion of tonsil when this was so large as likely to give rise to trouble. This drug also seemed to me to be attended with a risk which was unnecessary. I admit that in the "team work" described by the writers of the article in the *Journal* of July 28th (p. 149), the risk in their hands is reduced to a minimum. In clearing Rosenmüller's fossa the most efficient instrument is that introduced by Mr Golding Bird, the first of the post-nasal curettes (*Guy's Hospital Reports*, 1881, p. 446). While the tip of the foregoing protects the Eustachian tube the fossa can be effectually cleared of growth. Unless this is done Eustachian catarrh is liable to persist, and that complete recovery of hearing which should follow the operation may not be secured.

The objections raised to Clover's inhaler have no real foundation, provided it is properly used and the rubber bag cleansed with hot water after each administration. There should be no cyanosis, and though there is more bleeding than with chloroform it is never excessive or harmful. The re-breathing of the air is another objection, and this is fully met by admitting fresh air from time to time. The practice of employing gas or ethyl chloride before ether has, in my experience, led to delay, and prevented the quick and easy induction obtained with ether alone, while the preliminary employment of chloroform or A.C.E. was always a cause of anxiety. In making this statement I may add that in private and in hospital the administrators have been amongst the leading anaesthetists of the day.

When once the right use of Clover's inhaler has been understood the practitioner has in his hands a means of producing anaesthesia for a few minutes or for any required period and with complete freedom from anxiety. The fatalities that have attended this operation—and there have been many—have almost invariably occurred when chloroform has been employed. I have felt compelled when my advice has been asked as to the necessity of an operation to enquire on condition that ether be employed. This is not the occasion to discuss the operation itself though on several points raised in the discussion I should like to remark. It would also occupy too much space to describe the special points in the use of Clover's inhaler—I am, etc.,

London Aug 24th

CHARTERS J. SYMONDS

DISTALS OF THE CORONARY ARTERIES

SIR,—I am much interested in the instructive article on the above subject by Dr George A. Allan in your issue of August 11th (p. 232). I would have expressed my indebtedness to him sooner, but when he was conveying his cardiac message south I was enjoying a holiday in Scotland, which was, from a health point of view, much better for my coronary arteries than a dissipation in Cardiff. Since then I have been waiting patiently and fruitlessly for the flood of light which he anticipated would clear up the obscurities of this obscure subject.

Nearly fifty years ago Dr Mitchell Bruce sent me a German paper showing that in dilatation of the thoracic aorta the expansion chiefly took place in the direction of the greater curvature. Dr Bruce suggested that I might try to find out the cause of this undoubted fact. I soon did so, at least to my own satisfaction. At the time I was working on the effects of overwork on the heart and aorta, and I had already published a paper on the subject in the *Edinburgh Medical Journal*, 1876.

I found that this dilatation was due to longitudinal straining of the arteries owing to a great disparity between the systolic and diastolic pressures—which is now known as pulse pressure, a term very commonly used by many who have no knowledge of its cause or value. This dilatation was then very common in German beer drinkers. The low percentage of alcohol was quite sufficient to keep the peripheral vessels dilated, while the huge quantity of beer drunk kept the whole vascular system over-repleted, and this was necessarily associated with dilatation of the heart's cavities. The brunt of the large output from the left ventricle was thrown against the greater curvature,

the systolic pressure was raised, and thus resulted longitudinal and to a less extent lateral straining. The outflow was large and rapid, and consequently at the end of the cardiac systole there was a rapid fall in the arterial pressure. I have often shown that the velocity of the blood in the arteries, apart from the pulse wave, depends on the difference between the systolic and diastolic pressures—the maximum and the mean. This high and rather intermittent pressure led to degenerative changes in the deeper layers of the intima, with fatty or atheromatous deposits. When there was excessive quantity of lime in the blood it was at first deposited in the atheromatous patches as a calcium soap, and afterwards the fatty acid was replaced by phosphoric and carbonic acids. Hence there followed calcareous degeneration which frequently involved the mouths of the coronary arteries, and the large vessels arising from the greater curvature. This longitudinal straining with subsequent atheromatous degeneration affected the large superficial coronary arteries, and the large vessels at the base of the brain, while the terminal branches embedded in the cardiac muscle might be quite normal, and even the cardiac muscle red and healthy, until a late stage when myocardial degeneration set in. There is very seldom any cerebral haemorrhage in these cases, as the patients usually die from cardiac failure with fall in the blood pressure. Longitudinal straining is also present in a very marked degree in aortic incompetence. On the other hand, in cases of arterio-sclerosis with high lateral pressure, such as occurs in granular kidneys, there very frequently occurs rupture of a small artery into the internal capsule. In many of these cases the small coronary branches become involved and lead to myocardial degeneration and subsequent heart failure.

Many of the symptoms attributed to the coronary arteries are really due to the myocardium, and many of the cock-sure diagnoses are not established on the post-mortem table.

The subject of treatment is very interesting. Remedial measures may be very successful if the heart and aorta are dealt with before any very advanced lesions have developed—I am, etc.,

London, S.W., Aug. 25th.

JAMES BARR

THE DIAGNOSIS OF CORONARY THROMBOSIS

SIR,—Dr G. A. Allan (August 11th, p. 232) gives statistics which show that in at least 37 per cent. of necropsies coronary lesions are found, from the evidence of fibrosis half of these may have had coronary occlusion. If, therefore, one person in six has at some time some slight occlusion of the coronary arteries, we must all be meeting this frequently and not recognizing it, but labelling it something else. Clinical examinations for some years have convinced me that coronary thrombosis is common, and Dr Allan's statistics fortunately add another link to the chain of confirmation. Many patients in whom we have been diagnosing angina, pseudo-angina, cardiac dilatation, and myocarditis are really suffering from pericarditis, we do not recognize it because we have not been trained to look out for the signs and symptoms of an increase of fluid in the pericardium. Since I have learnt in the last few years to recognize these signs I have found that in persons over middle age a pericarditis of this type is quite common, I am seldom without a case under treatment, and I have labelled them "coronary thrombosis." By far the greater number recover, as from Dr Allan's statistics, they must have done in the past under another name, but an accurate diagnosis probably will lead to a better prognosis.

Taking Dr Allan's classification, I give the approximate number of cases in which I have made the diagnosis

(1) *Sudden death*. I have had three probable cases of coronary thrombosis though I had only one examination and there the suggestive patch was not examined microscopically.

(2) *Death in a few hours or days*. Of two cases in one there were gradually increasing signs for sixteen hours and the pericardial sac was enlarging the whole time. The second patient was improving and getting more comfortable but thirty-six hours from the onset had a cup of tea and in less than ten minutes was found dead without having made a sound, evidently a second and more severe occlusion.

(3) *Continual myocardial insufficiency with death in weeks or months*. One of my two cases was shown at the necropsy to have been due to gumma of the heart, the specimen is now in the Pathological Museum at Cambridge.

Of Dr Allan's classifications (4), (5), and (6), the milder cases, I should class all mine together, since all the patients spent, sometimes unwillingly, at least three weeks in bed. Of these I have had from thirty to forty, and all have recovered, apparently no worse for the adventure, though this is probably due to taking more care of themselves.

The first case in which I diagnosed the complaint was that of a man, aged 75, in September 1924. His illness began with sudden pain in the chest gradually increasing fluid in the pericardium and fever from the persistence of pain he was probably the most ill of those who recovered but he has continued to carry on his business as a building contractor, and I have found him in the last few weeks shovelling gravel quite unnecessarily. He has only been careful not to get breathless. But the great majority walk in to see me, with gradually increasing anginal symptoms which at once suggest a cardiac examination. In this week two have come in. One complained of continual chest uneasiness and had to stop three times on the way up to get case he was 77, and had never had heart symptoms before. The other suffered from chest uneasiness which would not let him sleep because he could not lie on the usual side, he was 67, and had for some months shown undue breathlessness.

Cases such as these are frequently seen by all of us, yet both had a swollen pericardial sac which increased day by day, one has now lost his uneasiness and is recovering the other is probably at the zenith.

The chief symptom is chest pain, and this, or at least some uneasiness, is continuous, it may get worse with exertion, but the consciousness of it is always present. The sternum is the main point, sometimes to the left shoulder or the pit of the stomach, but the sternum can always be found to be the centre. There is always evidence of an increase of fluid in the pericardium. It is on this that the diagnosis rests. It can be found almost at once, increases for the first few days, then remains stationary, and slowly disappears in about three weeks from the beginning. A friction sound I have only heard occasionally, and I am inclined to think, in the stage of recovery. The heart sounds are muffled, especially in the recumbent position, in the first day or so they are plainer when upright. The blood pressure is lowered, and with recovery returns to the patient's normal. In only the severe cases is there fever. In my patients in Class (2) the first had it, the second not, in Class (3) both patients had fever for the first few days. Of those who recovered, only my first patient mentioned previously had fever for a few days, the mild cases are afebrile throughout. But the main point in diagnosis is the increase of pericardial fluid, it may be found by light percussion, though I prefer to trust to auscultatory percussion, and here the right border of the heart's dullness is the important point. At the second rib it will be a very little outside the right border of the sternum, but the distance from the sternum gradually increases with each rib, till, in a bad case, it may reach the nipple, or be an inch inside it in a mild one. The left border of the heart will be an inch outside the nipple, but the slanting right line is the important finding. It has only to be looked for in the right way. I have always been able to get colleagues to find it and to detect it in other cases which I have confirmed.

In one case Sir Humphry Rolleston in consultation agreed with my findings and conclusions. That patient a retired medical man, has recovered can play his round of golf and since his attack over a year ago has been free from angina though before I saw him he had been diagnosed by a well known specialist as suffering from this condition. In the attack his blood pressure was around 105 but has got back to 130.

When recovery has occurred the right line of the heart's dullness will be parallel with the right border of the sternum and close to it; on the left it will be found about the nipple. The principal point in treatment is, of course, rest in bed, for drugs I pin my faith to opium, with a grain or two of potassium iodide. The mildest case will have 5 minims of tinct. opii three times a day, in the next stage, every four hours, and in more severe cases the dose is further increased. Vaso-dilators in the early cases were of no help, and with the natural lowering of the blood pressure I now never even think of them. But a mustard plaster over the pericardium till the skin remains reddened is probably of real use, it is certainly grateful to the

patient, except in the mildest cases. After the attack, for prophylaxis, I firmly believe in potassium iodide, and I think it does these urticulo-sclerotic patients good. It is taken for one week in the month, and to aid the memory the first day in each month is the day to begin the medicine.

The technique of auscultatory percussion is to place the stethoscope about the middle of the organ to be mapped out and gently tap with the tip of the finger from the stethoscope outwards, over the organ the note remains the same, but directly over taps beyond it the note alters. Practice is necessary, and perhaps, though I am not sure, a "musical ear." Besides practice the only caution I would give is not to percuss along but across a rib, for the rib will give its own note. There will be no difficulty in defining the size of the heart in the so-called emphysematous chest. The spleen may be found with a certainty that is not always attainable by palpation. In a case diagnosed as a huge spleen, by this method I found a normal spleen and a tumour arising from the pelvis, for the notes were distinctly different. My finding was subsequently confirmed at operation. Fluid in the chest can be diagnosed with certainty, for the note alters at the upper limit, while the uncovered lung has the same note right up to the apex. It is interesting that the note of fluid in the chest is conveyed over to the opposite side, Grocco's triangle is exactly marked out at the upper limit, so that the swollen pleuritic sac does actually bulge out to the other side. The shape of the stomach and its alteration from the recumbent to the standing position can be mapped out like an x-ray picture. The spleen and the liver will be found larger than in the cadaver, and the upper limit of the liver dullness is always an astonishment.

I am sure no one will regret the time given to practice when he has obtained a working acquaintance with auscultatory percussion, but this will not come quite easily or at once. It is worth learning if only to confirm ordinary percussion and give to it a certainty which is denied to most of us in all cases.—I am, etc.,

W. R. GROVE, M.D.,
Honorary Medical Officer, Huntingdon
County Hospital

August 18th.

HERMAPHRODITISM

Sir,—The interesting account of a case of tubular partial hermaphroditism of the external type recorded by Mr. Harold Hartley and his discussion thereon (*British Medical Journal*, August 25th, p. 342) raise two important questions—namely, what is the legal definition of sex, and what should be the social upbringing of the person affected?

I have always been under the impression that the sex of a person depends in law on the nature of the gonad, and in my book *The Sex Complex* I have discussed the difficulties of this position, which become accentuated when there is an ovotestis. I should be glad to learn what is the authoritative legal ruling on this matter at the present time.

With regard to the upbringing of a partial hermaphrodite, Mr. Hartley rightly states that most British medical authorities have advised that the subject should always be reared as a boy, owing to the greater frequency with which the gonad is of the male type (see Nagebauer's *Hermaphroditismus*). I have, however, recorded¹ four similar cases of tubular partial hermaphroditism of the external type, seen by me within the space of a few months in all of which there were ovaries.

Mr. Hartley further states that I have not accepted the above doctrine and have advised that the sex of the individual should be assessed according to the character of the external genitalia, and that the person should be brought up accordingly. This statement does not expound my views quite correctly.

All tubular partial hermaphrodites have secondary characteristics, both physical and psychological, of a sex-type opposite to that of the gonad, and usually (but not in the very rare internal tubular type) external genitalia in con-

formity with the general secondary characteristics. I have therefore recommended that partial hermaphrodites should be brought up in accordance with the predominance of the secondary characteristics, and this will usually mean according to the appearance of the external genitalia—a fortunate circumstance, for the general secondary characteristics may not be pronounced in childhood. Where, however, there is simply a hypertrophied phallus associated with ovaries the case may require different consideration.²

It must be remembered that when the external genitalia resemble the male type the external genital folds are rarely united, so there is no penile urethra or scrotum, and care must be taken to exclude hypospadias in the male in such cases. When feminine the external genitalia are true to type, and in these circumstances the secondary characteristics correspond, and, as in Mr. Hartley's case, the person is always regarded as a woman. I have known more than one happily married.

Operative intervention to alleviate the disability present is a matter for serious consideration in many cases, but I cannot here enter into this aspect of the problem. Those who are interested, and find this brief discussion incomplete, will glean further information from the references given. It is a highly important matter from the legal point of view in regard to inheritance and marriage, and it is one to which forensic authorities should turn their attention in the light of modern knowledge.—I am, etc.,

Liverpool Aug 31

W. BLAIR BELL

THE CURSE OF NOISE

Sir,—I am convinced that the majority of motorists—be they drivers of motor cars, motor cycles, or heavy motor vehicles—never knowingly use their horns or drive noisily when passing hospitals, infirmaries, and nursing homes, but in many cases the stinger is quite unaware of the purpose of the buildings adjacent to the road upon which he or she is proceeding.

The Automobile Association has erected tons of thousands of road signs specifying the nature of unseen dangers, in particular schools, cross-roads, dangerous corners, concealed turnings, level crossings, etc., leaving it to the good sense of the motorist who is strange to the district to drive in the expectation that children, cross traffic, or closed gates may be encountered.

If, however, there is a general demand on the part of institutions tending the sick and convalescent for the erection of signs, I shall be pleased if those in charge will communicate with me, when I will arrange for an inspection to be made. As more signs of this type are provided and erected, appeals will be issued to all motorists to refrain from disturbing patients by unnecessary use of the horn or noisy driving.—I am, etc.,

Fanum House, New Coventry
Street W 1, Aug 28th

STENSON COOKE,
Secretary Automobile Association.

SEA-SICKNESS

Sir,—In a letter on sea sickness (*August 25th*, p. 357) Dr. Blair says he "is surprised that no one has mentioned the respiratory disturbance associated with this malady."

In my student days in the early eighties a correspondent in one of the medical papers suggested as a cause of sea-sickness the disturbance of the respiratory centre caused by irregular respiration due to the pitching of the vessel, a disturbance which affected the adjacent vomiting centre. To test this the writer said that on a voyage from Tasmania to Australia he had taken a number of the passengers who were notoriously "bad sailors" up into the bows of the vessel (where the pitching would be more felt), and had induced them to breathe regularly by the raising and lowering of his hands about eighteen times a minute, the experiment was successful in that most, if not all, of them got through without any sickness.

I remembered the suggestion some years later when I was crossing from Southampton to Jersey one very rough night,

¹ *Amer. Journ. Obstet.* 1925, x 778.

² *Amer. Journ. Obstet.* 1925, x 778.

feeling the onset of sickness, the concentration of my attention on maintaining a regular respiration served me well.

On another occasion I was in a small yacht in the North Sea with three other amateurs. It became rough, and there was difficulty in managing the boat. To my dismay, the one of the four who knew more about sailing than any of us had to retire to the cabin and leave us to manage the boat as best we could, because he was beginning to feel sick. Again I remembered the suggestion, and I persuaded him to breathe regularly to the raising and lowering of my hands. After ten minutes or a quarter of an hour he said "Thank you, I feel better. I will lie down again, and I think I shall soon be all right." But presently he came back to me and said that he felt the sickness coming on again, would I set him breathing once more? With that his trouble passed off entirely, and he was able to take his share in managing the boat.

Dr Blau may like to know that his suggestion has been tried and found to be effective—I am, etc.,

Tunbridge Wells, Aug 27th

ARNOLD C INGLE

Sir,—I venture to think that an experience of my own may perhaps throw some light on the cause of sea-sickness in certain cases.

About two years ago I paid a visit to America. I had never before been on the sea for more than thirty hours, and was glad to find that I was not sea-sick on the outward journey, although the boat rolled 30 degrees or more. I quite expected to be immune on the return voyage.

About the second morning out, after an early bath, I went to the gymnasium for the customary "table" of exercises before breakfast. The gymnasium felt very hot (it most likely was so), and I felt myself perspiring about the face, which was unusual. It was only when returning to my cabin and feeling sick that I realized, and with considerable surprise, that I was in for sea-sickness.

Some of the usually alleged causes, although no doubt operative in some cases, can, I think, be excluded in mine. Visual impressions can hardly have had anything to do with the matter as the gymnasium commanded no view of the outer world. The movements of the exercises were so violent that any motions of the semicircular canals due to the rolling of the ship would form but a small part of the whole, and would probably be negligible. I think suggestion may be ruled out on this occasion on subjective grounds, although it might well act on any future occasion.

There is, however, one very important difference between a man on shore and the same man on a ship, which would be described by physicists as the difference between "accelerated" and "unaccelerated" frames of reference—a rolling ship being a good example of the former and the solid earth the very best instance (to us humans) of the latter. As to this being a possible cause of sea sickness I would refer to the work of Sir C. Sherrington on the sympathetic control of voluntary muscle; he pointed out that over and above all other controls there existed a sympathetic nerve mechanism, the function of which was to maintain a "normal" or "world right side up" posture. The co-ordinations of this mechanism suited to a stable earth would not function correctly on a rolling ship or in an earthquake. As we all know, conscious balancing is made use of on such occasions, but, underneath all conscious action, the unconscious mechanism will be doing its best to deal with the disorderly crowd of sensory impulses coming in from the skin, muscles, joints, and semicircular canals, and it will be greatly overworked.

I do not know what would be the result of that continued strain, but wonder whether it might not cause sufficient disturbance of related systems, both sympathetic and cerebral, to evoke the disorders of action and feeling that are called "sea-sickness."

If this is so, the recovery from sickness would correspond to the re-education of the sympathetic mechanism so that it could effect co-ordinations suitable to a moving "base"—I am, etc.,

J B PARFITT

TREATMENT OF PUERPERAL SEPTICAEMIA

Sir,—In the year 1925 the death rate recorded in England and Wales from puerperal septicaemia was equal to 1.56 per 1,000 births, and in 1926 1.60. In Ipswich the puerperal septicaemia death rates were 2.81 and 1.30 respectively. Thus, the local mortality experience was rather worse than that of the country as a whole.

For many years cases of puerperal septicaemia have been admitted into the Ipswich Isolation Hospital. The results of treatment were not good, because only a small number of the very worst cases were received as a last resort, with, in consequence, a very high mortality experience. Since the war a greater number of cases have been admitted to the hospital, and during recent years a determined effort has been made to unearth the actual cases and secure hospital treatment. As a result, between 1919 and 1924 inclusive, 23 patients with all types of puerperal sepsis were admitted, of whom 8 died—a case mortality of 34.78 per cent.

Between the beginning of 1925 and the moment of writing 27 cases of puerperal sepsis have been admitted, with one death, a case mortality of 3.7 per cent. The type of case during the last period was much the same as that of the earlier, in other words, type was not the factor determining the mortality experience. In both periods certain procedures were common, such as the sitting-up position for drainage purposes, the systematic use of enemata, the administration of drugs, such as quinine and pituitin, to promote uterine contraction, vaginal douches as indicated, and the injection, as deemed advisable, of doses of 30 to 40 c.c.m. of antistreptococcal serum.

The sole difference between the two groups of cases lies in the fact that, in the series treated since 1925, colloidal argenticum has been given intravenously—in adequate dosage as the results would appear to indicate. In the first series colloidal argenticum was given intravenously in a few cases, but in doses too small to be effective. I have come to the conclusion that the dose should be not less than 15 c.c.m., and probably not more than 25 c.c.m., as doses of 20 c.c.m. have, on occasion, produced rigors. It is difficult to believe that a dosage sufficient to produce a rigor can be without risk. These doses should be repeated daily for four or five days, should the fever last so long, but in my series the only case in which the temperature remained up over five days was the one subsequently proving fatal.

In the limits of a brief statement such as this it is impossible to discuss the way in which the colloidal silver may act, but, in my opinion, a case has been made out suggesting that, in intravenous doses such as have been indicated, the remedy is well worthy of investigation, not only in puerperal sepsis, but in other septicæmic conditions. The drug, so far as my experience goes, is without injurious effects either generally or locally. If there is any local disturbance it is transient and can be disregarded. In this respect colloidal argenticum has very considerable advantages indeed over drugs such as mercurochrome. Lastly, I would emphasize that the drug must be given intravenously.—I am, etc.,

LATERAL RADIOGRAPHY OF THE URINARY TRACT

Sir,—The paper on "The diagnosis of ureteric calculi" by Professor Fullerton, published in your issue of August 25th (p. 327) would appear to raise an immediate question concerning the most accurate method of localizing and confirming the nature of doubtful shadows in the urinary tract.

Professor Fullerton, in introducing the technicalities of radiological examinations, stated that the subject was a large one and could not be embraced in the compass of his paper. I venture to suggest, however, that the omission of some mention of lateral radiography of the urinary tract was a grave one, and that its exclusion in favour of stereoscopic radiography was unfortunate and misleading. Radiological examinations are becoming an integral part of the clinical procedure adopted in investigating a patient

presenting symptoms of urinary dysfunction, and one feels that every effort must be made to insist upon a routine in the methods employed by the radiologist in presenting his contribution to the picture. Stereoscopy must necessarily place the localization of doubtful shadows almost entirely in the hands of the radiologist and make his opinion an omnipotent one, it is not always possible to convince another that the eyes could not have been deceived, and the difficulties of recording an impression are obvious. The technical errors which can arise in carrying out stereoscopic x-ray examinations are well known to those who have had considerable experience in localization.

While admitting the value of stereoscopy in selected cases, I believe that very much more accurate and convincing information can be gained by obtaining right and left lateral radiograms of the whole urinary tract under modern conditions a lateral radiogram of the lower portion of the ureter presents little difficulty. By means of a lateral series of films the site of urinary shadows can be demonstrated and permanently recorded, and the subsequent pyelography or urography be undertaken, when necessary, without fear of injury to the patient's skin by an accumulative erythema dose.

Lateral radiography appears to have been sadly neglected in the past, and I think it must be agreed that its inclusion in pyelographic examinations as well as ordinary x-ray examinations of the urinary tract is of great importance—I am, etc.,

London W 1, Aug 25th.

L. J. H. ROTH

THE ALLEGED HIGH FERTILITY OF JEWS

SIR,—In the report on August 18th (p. 310) of the discussion on the falling birth rate held in the Section of Medical Sociology of the Annual Meeting of the British Medical Association Dr Lotitia Farnfield is stated to have referred to the high fertility among Jews.

The contention that Jews are a prolific race is being made repeatedly, though all the facts point to the contrary. It is true that Jews have the injunction to "increase and multiply and replenish the earth," and that Biblical history records that in Egypt "the children of Israel were fruitful, and increased abundantly, and multiplied and waxed exceedingly mighty and the land was filled with them." It is also true if Biblical statistics are to be accepted at their face value—that the 70 souls that migrated with Jacob increased in the space of 430 years to about 3,000,000 (603,550 males "from 20 years and upwards all that were able to go forth to war in Israel").

But Biblical commands and statistics are no criteria of conditions obtaining in modern days. The fertility of the Jews was probably high during the beginning of the last century, but towards the latter part conditions had changed enormously. With the political emancipation of the Jews in Western Europe, a great weakening of religious fervour occurred, with a consequent disregard of Biblical injunctions. The Jewish birth rate declined rapidly, and in many places fell much below that obtaining among the non-Jewish communities, as can be seen from the following table,¹ which refers to the period at the beginning of the present century.

Births per 1000 Population

	Jews	Non-Jews
Berlin (1905)	17.7	25.5
Frankfort-on-Main (1905)	16.2	29.1
Prague (1901)	15.8	31.3
Bavaria (1906)	18.2	36.0
Prussia (1903)	17.0	33.0
Bohemia (1900)	17.8	34.9

The decline in the birth rate in most European countries, which is engaging so much attention, is thus not only seen among Jews—but is found among them in a most accentuated form. To what extent the birth rate among Jews can fall is also seen from the following comparison for Vienna—

Birth Rates in Vienna

	Jews	Non-Jews
1900	22.2	21.7
1923	13.5	16.4

¹ Fishberg, M. *The Jews*, p. 23.

² *Mitteilungen des Bundesamtes für Statistik* Wien.

It is also worth noting, that during the past two years the number of deaths in Viennese Jewry has exceeded that of births.

The state of affairs in London can only be judged on indirect evidence since, unfortunately, there is no denominational census in England. It appears that, contrary to conditions seen in other Western countries, the birth rate among Jews in London was actually rising towards the end of the last century² (this was probably due to the heavy immigration at that time into London of poverty-stricken Jews from Eastern Europe). But since then the birth rate among Jews in London has not only been declining, but doing so to a greater extent than the rate among non-Jews, as can be seen from the fact that in Stepney, where the Jews are crowded together, the fall in the birth rate has been more marked than in comparable districts of London. This is shown by the following table⁴:

Birth Rate per 1000 Population

	Stepney	Poplar	Southwark	London
1903	38.1	35.1	33.7	8.8
1927	18.3	19.8	19.0	16.1

It is thus seen that far from leading with the highest birth rate the decline in the birth rate in Stepney has been greater than for London as a whole—52 per cent against 44.

As against the fact that the rate for Stepney is higher than that of London as a whole (18.3 as against 16.1) must be set the fact that Stepney harbours the poor among the Jews, so that when the presumably lower birth rate of the wealthier Jews is considered, it must be concluded that while the birth rate among poor Jews is lower than among the comparable non-Jewish population, the birth rate among Jews as a whole is as low, and probably lower, than that of London as a whole.

It is not necessary to labour the point. The figures for London are in agreement with those of other centres in showing that the declining birth rate is presenting an even more acute problem to Jewry than to other communities. There is certainly no justification for speaking of a high fertility among Jews—that is now a thing of the past.

I am obliged to Mr D. Tcherniakoff, B.Sc., the secretary of the Jewish Health Organization of Great Britain, for some of the data in this letter.—I am, etc.

M. SOLARSKY, M.D., I.R.C.S.Ld.

London W 1, Aug 19th.

RESULTS OF TREATMENT OF UTERINE CANCER

SIR,—On returning from abroad my attention has been called to a letter by Mr Victor Bonney in the *British Medical Journal* of July 21st (p. 128). In it he takes exception to certain figures quoted in the first report of the Cancer Research Committee of the London Association of the Medical Women's Federation. As I was largely responsible for these figures perhaps you will allow me to reply.

The report was compiled in the spring of 1925, and was in the press before Mr Bonney's 1926 paper was published. The figures quoted are substantially the same as those produced by Mr Bonney in his paper in the *British Medical Journal*, 1921, vol. 11, p. 1105, and agree with the results recorded in Berkeley and Bonney's *Gynaecological Surgery*, second edition, p. 401. Mr Bonney subjects his figures to many minor deductions and variations. We regret that we did not include the complete bibliography, but only gave the reference to his most recent publication.

Apart from the lessened operative mortality to which we referred, the most recent results given by Mr Bonney, and based on a larger number of cases, are practically identical with those given in his earlier papers. The figures we quote make his results appear even slightly better than those which he now claims are correct.

It would appear from Mr Bonney's figures that for many years surgeons have been unable to improve materially the results obtained in the treatment of this disease. Our report was an attempt to compare the surgical results in cancer of the cervix with those which

³ Royal Commission on Alien Immigration. Minutes of Evidence. 3357.

August 28th.

IONIZATION FOR NON-SUPPURATIVE OTITIS

SIR,—I read with much interest your review of the work of Drs Landry and Franquet of Rheims on the effect of ionization in non-suppurative otitis. I have, for the past eight or nine years, used and advocated this method as part of the routine followed by me in cases of middle-ear deafness, excluding otosclerosis. Certain selected mixed cases have, however, also had the same treatment. The clinical results obtained led me to the belief that the drug passed to the desired site and produced the expected result of reabsorption. It is of the utmost importance that the experiments recently carried out at Rheims appear to confirm this view. My best results have so far been obtained with potassium iodide and sodium chloride—I am, etc ,

Bath Aug 25th.

H NORMAN BARNETT

PRESTON HALL TUBERCULOSIS SETTLEMENT

SIR,—In your review of the British Legion Village Settlement report (August 25th, p 354) "according to newspaper accounts over 50 per cent of the settlers will be thrown out of employment," as a result of the fire which occurred here on August 12th. This is far from representing the true state of affairs, for, actually, not a man has lost one hour's work. It is gratifying also to report that as a result of improvisation in workshops and machinery, goods were actually delivered in the open market in less than seventy-two hours from the time of the outbreak of the fire—I am, etc ,

Aylesford Aug 27th.

J B McDONNALL,
Medical Director

Obituary.

THE LATE LADY OSLER

THERE must be few women who have enjoyed a wider reputation amongst members of the profession than the late Lady Osler. This was due, in great part, to the fact that she was the wife of the late Regius Professor of Medicine at Oxford. Apart from this, however, she had a personality of her own which was most attractive, and many from far and near have been the recipients of her hospitality. Indeed, during Sir William Osler's lifetime, her duties as a hostess were often so exacting as to impose a serious strain on her physical resources. It may not be amiss to recall some of her other activities and to place on record some of the virtues that endeared her to her many friends and acquaintances. Begotten of a stock illustrious in the history of America, Grace Revere was the great granddaughter of Paul Revere, whose memorable ride was immortalized by the gifted pen of Longfellow. He was a remarkable man in other ways—an engraver of wide repute, a craftsman of great skill in the working of silver and other metals, an accomplishment which laid the foundation of a prosperous career. As a young woman Grace Revere married Professor S W Gross of the Jefferson Medical College, Philadelphia, whose father at that time was America's most distinguished surgeon. As a young wife she acted as hostess to her father-in-law's numerous guests, and early acquired that grace and charm of manner which subsequently became such an attractive feature of her personality. Left a widow, she married in 1892 Dr William Osler, then the most brilliant and accomplished physician in the United States. In the spring of 1905 she came to Oxford with her husband, who had been appointed Regius Professor of Medicine. Ever since she has identified herself with the interests of Oxford and its medical school. As Sir William Osler's wife she shared in all his responsibilities. It was an ideal partnership. As his widow she was eminently successful in carrying on

the traditions he had left. Of a nature most generous and bountiful, she spared no pains to befriend the afflicted, and during the early years of the war she was most helpful, for, through her influence in America, she was the means of obtaining large sums of money to succour the wounded and relieve those sorely stricken. Her sympathy was very real with those in sorrow, for she, too, had suffered by the loss of her only son. Her interests were in later years centred in the welfare of the Radcliffe Infirmary, of which she was a member of the board of management. One of the duties of which she was most proud was her appointment as a trustee to the Evelyn Charities. This enabled her, after the death of Sir William, to retain her association with the old-world village and its picturesque almshouses. So, too, the Regius Professor's connexion with Christ Church was responsible for her devoted interest in the Christ Church Mission.

It was largely due to Lady Osler's personality that her home in Norham Gardens became one of the social centres of Oxford. There one would meet men of world-wide reputation side by side with the youngest "fresher," who had come to present his letter of introduction to the high-hearted "Regius" and his lovable wife. There, too, she exercised a motherly care over many of the friendless ladies who had been attracted by the lure of Oxford, amongst whom may be mentioned especially the American Rhodes scholars, who found a home when far from home. Her influence has done much to draw closer the bonds which link together the youth of kindred stock and tongue. Her dignified presence, her charm of address, and her sincerity of purpose, coupled with a tenderness essentially feminine, has ensured, amongst those who were privileged with her friendship, a memory ever fresh and desirable. This counts for much, and is, alas! all that is now left to us.

A T

DR EGERTON CHARLES GREY, who died suddenly from pneumonia on August 10th, had recently been engaged on research work for the League of Nations, and was formerly professor of chemistry at the University of Cairo. He was the second son of the late Colonel Arthur Grey, and was educated at Cambridge, where he was a member of Emmanuel College, proceeding with his medical studies at Guy's Hospital, London. He obtained the diplomas M R C S and L R C P in 1918, graduating M A Cantab and D Sc Lond two years later. Previously he had served during the war as a subaltern with the Royal Fusiliers and had been wounded at Gallipoli. After being invalided from the army he later joined the R N V R as a surgeon probationer, and took part in the operations in the Black Sea. Subsequently, while Foulerton Student of the Royal Society, he was appointed professor of chemistry in the University of Cairo, then in process of formation, he was the first general secretary of this body, and for his services in Egypt received the Order of the Nile. Dr Grey resigned his post in Cairo to undertake research work for the League of Nations on the food problems of Japan, the results of his investigations have only recently been published at Geneva. His scientific work was directed mainly to the study of the chemistry of fermentation, which was the subject of many of his numerous contributions to the *Proceedings* of the Royal Society. He was a member of the British Medical Association, in which his brother, Dr F Temple Grey, is a prominent member of the Marylebone Division. A colleague writes: A great admirer of Pasteur, Dr Egerton Grey's work was distinguished by scrupulous accuracy and attention to detail. A man of lofty mind, broad vision, and extraordinary generosity, he will be sorely missed by those whose privilege it was to know him.

Dr J E MOORHOUSE, who died after a short illness on August 17th, at his residence in Stirling, was born in Yorkshire in 1869, and graduated in arts at St Andrews, where he obtained the degrees M A and B Sc in 1889. He afterwards proceeded to Edinburgh and studied medicine, obtaining the degrees M B, C M in 1892, and becoming M D in 1895. After holding an appointment as resident physician in the Royal Maternity and Simpson Memorial

Hospital at Edinburgh he removed to Stirling, at the time of his death he had been in practice there for some thirty-six years. He was a medical referee under the Workmen's Compensation Act, and until recently had held the appointment of surgeon to the Stirling Royal Infirmary, he was also for a number of years medical officer to the troops stationed in Stirling Castle. In spite of the claims of a large practice Dr Moorhouse took a constant interest in scientific medical progress, he was a member of the Medico-Chirurgical Society of Edinburgh and a Fellow of the Obstetrical Society of Edinburgh and frequently attended their meetings. He was a member of the British Medical Association and in 1906 was actively engaged with Dr Burt in the compilation of evidence from a questionnaire on Poor Law administration, which was sent to Scottish Poor Law officers. Dr Moorhouse represented the Stirling Branch on the Central Council in 1914, 1915, and 1916. He was a man of kindly and sympathetic manner, much beloved by a large circle of friends and patients, by whom he will be greatly missed. He is survived by a widow and one daughter. A colleague, G. C. S., writes: Dr James Moorhouse was one of those men who devote time and labour without stint to further the interests of our Association. For many years, it might be said, he was the Stirling Branch. Any knotty question of Association business or procedure which was referred to Moorhouse was promptly cleared up. When I succeeded him, for a year or two in the secretariatship of the Stirling Branch, it was a joy and deposal to turn over his minutes: they were so exact, concise, and in such beautiful script—a model of what minutes should be. In addition to his business abilities Moorhouse was of the type of scholarly physician, happily by no means extinct, although less common, I think than in former days. To him may be fully applied the words of Ausonius:

*Obitu opem cunctis poeuitibus artis membrae
Obiitumque meum cum pietate fuit*

which remain after the "mountains of gold" gained by one of the Roman court physicians have passed away.

We regret to announce the death of Dr MARY J. McNEILL, which occurred at Jugha Hospital in East Africa on June 10th for the past seven years she had been engaged in medical work in association with Roman Catholic missions in Uganda. Her name will be remembered in connection with the fine work rendered by the Scottish Women's Hospital in Salonika during the war. Born in 1874 in Orkney, she was the eldest daughter of the late Rev Daniel McNeill, M.D., and, after studying in Germany and Switzerland, received her medical education at Queen Margaret College, Glasgow, graduating M.B., Ch.B. in 1905. She then commenced practice in Orkney, remaining there until 1914, when she went to Leicester to free her brother for service with the Royal Army Medical Corps. Two years later, after serving for a period as resident physician in the Leicester Fever Hospital, she joined the staff of the Scottish Women's Hospital in Salonika, proceeding thence to Belgrade in Serbia in 1919. Subsequently she went to Palestine to take up an appointment as assistant medical officer to the Scottish Hospital at Tiberias, and later became medical officer in charge of the Scottish Mission Hospital at Bhandara in India. In 1921 she joined the Roman Catholic Church and was attached to the Catholic African Mission at Kampala, Uganda. Latterly she worked single handed with three Franciscan sisters at a remote and isolated station at Kamali, Busoga, and was looking forward to coming home on leave in November. A colleague writes: Those who knew Dr Mary McNeill loved her for her upright character, her unselfish life, her devotion to her family, and her loyalty as a colleague. The deep joy she took in living was a source of inspiration to her friends. She had a great interest in literature and art, and a marked gift for writing and for poetry. Dr McNeill never lost her youthful interest in people and places, she had travelled extensively and absorbed new ideas and made friends wherever she journeyed. The loss to her family is irreparable, and her passing has left a great gap in the hearts of her friends. She might well have been called the "beloved physician."

We have to announce with regret that Khun Bahadur Dr DOMINION PRATON COOPER died at Surat on June 4th, at the advanced age of 93. He was educated at the Grant Medical College, Bombay, where he won the Cairns scholarship, and obtained the diploma of Graduate of Grant Medical College in 1863, eleven years before the foundation of the University of Bombay. He was one of the band of practitioners whose pioneer work for Western medical science has stood the test of time and paved the way for the advancement of education in General and medicine in particular. He played a considerable part in public affairs, and served as a member of the borough council of Surat for an uninterrupted period of nearly fifty years—from 1867 until 1916. He was a first-class honorary magistrate of Surat, a Fellow of the University of Bombay, honorary assistant surgeon to the Viceroy in 1885, and was awarded the Kaiser-i-Hind Silver Medal. At the beginning of his career Dr Cooper was appointed medical officer to the Parekh Dispensary, Surat, at Naupura. There he did much to popularize vaccination, and rendered yeoman services in obstetrical and gynecological relief in the early days of the ignorant and superstitious native "dai." He was the first president of the Surat Medical Association, founded in 1886, and in 1887 he was awarded the distinction of Khan Bahadur for his public services. He was probably the oldest Freemason in India at the time of his death, having, in 1871, joined the Lodge Rising Star, which was founded in 1844 by Dr Barnes, under the auspices of the Grand Lodge of Scotland. Dr Cooper leaves a large family of sons, several of whom have achieved distinction, Mr Dhunjee-shaw Cooper is a sessions judge at Surat, Dr Ardeshr Cooper was formerly sanitary commissioner for the Baroda State and Dr K. D. Cooper is chief medical officer to the Bombay Electric Supply and Tramways Company. Sir Temulji B. Nariman, President of the College of Physicians and Surgeons, Bombay, writes: "I had known the late Dr D. P. Cooper from my college days—that is, from 1867. He rendered very valuable services to the city of Surat, both as a municipal councillor and as a practising physician, and his death will be greatly felt by both the poor and the rich of the city. He was a trusted Government servant, and once acted as civil surgeon, Surat, at a time when these posts were reserved solely for I.M.S. men. I shall miss him both as a personal friend and trusted colleague in the university. He was a man of genial disposition and noble character, and of great professional ability, and gave freely of his time and advice to suffering humanity, by whom his memory will be highly cherished. Thus passes one of the original, oldest, noblest, and strongest representatives of Western medical science in India, the fruits of whose efforts are just beginning to be realized."

Dr OGLETHORPE WAKELIN BARRATT BROWNING, who died suddenly on August 28th, in his 28th year, was a son of the late Samuel Browning of Birmingham, and received his medical education at University College Hospital, London, obtaining the diplomas M.R.C.S. and L.R.C.P. in 1925. Soon afterwards he contracted encephalitis lethargica while working for the M.B. degree of the University of London. His condition improved considerably for a period and it had been hoped that he would eventually be able to resume his work. As a student he showed great promise, and his death has caused much regret among his friends, who, although he was of a retiring disposition, were numerous.

We regret to announce the death on July 21st, at the age of 80, of Professor PANAGIS CAVADIAS, who occupied the chair of archaeology at Athens, and was an honorary member of the Section of the History of Medicine of the Royal Society of Medicine. He took an active part in the excavations of the Acropolis at Athens, and of the shrine of Asklepios at Epidaurus, where he was working until shortly before his death. His son, Dr Alexander Cavadias, is now in consulting practice in London.

The Services

DEATHS IN THE SERVICES

Brevet Colonel Alfred Goodwyn Kay, R.A.M.C. (ret.), died at Lymington on July 9th, aged 74. He was born on May 16th, 1854, and was educated at Edinburgh, where he graduated as M.B. and C.M. in 1879, after taking the L.R.C.S. Ed. in 1876. Entering the army as surgeon on February 5th, 1881, he became lieutenant colonel after twenty years' service, and retired on December 23rd, 1908. He served in the Egyptian campaign of 1882, receiving the medal, with the Khedive's bronze star. From March, 1900, to November, 1902, he was on the staff of the Commander in Chief in India. After retirement he was employed as recruiting officer at Clifton, Bristol. He rejoined for service in the recent great war when he was in charge of the Royal Victoria Hospital at Netley, and for his services received a brevet colonelcy on June 3rd, 1917.

Lieut. Colonel William Lloyd Reade, R.A.M.C. (ret.), died in London on June 30th, aged 69. He was born at Port Arlington on February 21st, 1859. After taking the Edinburgh double qualification in 1881, he entered the army as surgeon on July 30th of that year, attained the rank of lieutenant colonel after twenty years' service, and retired on August 14th, 1912. He was stationed at Hong Kong in 1896 when the great pandemic outbreak of plague—which is still going on, more than thirty years later—was imported into the colony from Southern China. He was employed on special duty combating the plague in Hong Kong, and was afterwards transferred to India when the disease became virulent there and employed as special plague officer at Poona during the years 1897-98. He served in the South African war of 1899-1902, receiving the Queen's medal with three, and the King's medal with two, clasps. He was also re-employed from August 15th, 1915, during the recent great war.

Lieut. Colonel Francis Patrick Staples, R.A.M.C. (ret.), died at Strawberry Hill on July 11th. He was born at Bally Cogley, County Wexford on December 14th, 1838, took the M.R.C.S. in 1860 and the L.K.Q.C.P. in the same year, subsequently becoming M.K.Q.C.P. in 1880. Entering the army as assistant surgeon on April 1st, 1861, he reached the rank of brigade surgeon on September 20th, 1887, and retired on February 1st, 1888. He served in the Hazara campaign on the North West Frontier of India in 1868, receiving the frontier medal with a clasp. In 1879-80 he was assistant professor of military surgery in the Army Medical School at Netley. During the old regimental days he served as assistant surgeon in the 19th Foot, the Green Howards.

Captain Leshe Graham Blackmore, R.A.M.C., died in a nursing home on July 2nd, aged 36. He was born on December 26th, 1891, the younger son of Mr. and Mrs. Herbert Blackmore of Gloucester Gardens, Hyde Park. He took the M.R.C.S. and L.R.C.P. Lond. in January, 1917, and, joining the Special Reserve of the R.A.M.C. immediately after, was at once mobilized as a lieutenant in the R.A.M.C., became temporary captain on April 1st, 1919, and captain from August 5th, 1920. He served during the latter two years of the recent great war.

Medical News.

THE annual dinner of past and present students of King's College Hospital will be held at 7.30 p.m. at the Trocadero Restaurant Piccadilly Circus, on Wednesday, October 3rd. Dr. B. R. Turner will be in the chair, and the donor secretaries are Dr. Ernest Playfair and Dr. H. A. Richards.

It is announced that the new laboratories of the Safety in Mines Research Board, upon which the Medical Research Council is represented, will be formally opened by the Prime Minister on October 11th. The new station which is situated at Sheffield, will serve as a national centre for scientific research into problems bearing upon safety in coal mines. Funds for this and for other purposes connected with miners' welfare are derived from a levy of 1d. a ton on the output of all coal mines, imposed by the Mining Industry Act of 1920. The expenditure of this revenue is vested to a statutory committee appointed by the Board of Trade, the Research Board advising this committee on the expenditure of any fund set aside for research.

A POST GRADUATE course for medical practitioners of the district will be held by the members of the medical and surgical staff of Addenbrooke's Hospital Cambridge, from Tuesday, October 2nd to Friday, October 5th. The course will begin at 2.30 p.m. and end at 4.30. Further particulars can be obtained from Dr. Aldren Wright, Cambridge.

THE Fellowship of Medicine and Post Graduate Medical Association announces that from September 11th to October 5th the Superintendent of the Bellem Royal Hospital will give a course of lecture demonstrations in psychological medicine on Tuesdays and Saturdays at 11 a.m. From September 17th to 29th, the Westminster Hospital will provide an all day course in medicine surgery and the specialties. An all day course in diseases of children at the Queen's Hospital, an all day course in orthopaedics provided by the staff at the Royal National Orthopaedic Hospital, and an afternoon course consisting of lecture demonstrations at the Royal Eye Hospital, Southwark all of a fortnight's duration, also begin on September 17th. Copies of all syllabuses, and information regarding the general course at the hospitals affiliated to the Fellowship of Medicine, may be obtained from the secretary J. Wimpole Street, W.1.

COMMENCING on September 17th a practical post graduate course in methods of examination and diagnosis will be held at the Central London Throat, Nose, and Ear Hospital, Gray's Inn Road, W.C.1.

THE Ministry of Health has issued a circular (No. 903) to sanitary authorities in England and Wales stating that instances have been brought to the notice of the Minister of the failure of local authorities to observe in the distribution of poisonous liquid disinfectants the provisions in regard to the shape and labelling of bottles made applicable to the retail sale of liquid poisons by various Acts of Parliament and regulations in view of the danger attending the use for the distribution of disinfectants of receptacles such as beer bottles, which ordinarily contain liquid intended for consumption. The Minister considers it desirable that the precautions taken in the sale of poisonous disinfectants should be observed also when they are distributed gratuitously or otherwise by a local authority. It is the Minister's view that in the public interest all poisonous disinfectants should be supplied only in containers distinguishable by touch from ordinary bottles, and that the containers should be labelled boldly in red with the words "Disinfectant—Poison—Not to be Taken."

THE annual congress of the National Veterinary Medical Association was held at Newcastle-on-Tyne from September 1st to 7th. Professor F. A. E. Crew discussed the nature of resistance to disease, and Professor R. G. Eliot dealt with the adulteration of foods as concerning animals. Mr. H. T. Matthews of the City of Liverpool Veterinary Department gave an address on the place of the veterinarian in public health. He emphasized the need for co-ordination of the medical, veterinary, and sanitary services in connexion with certain problems, notably in the control of meat and milk, suggesting that if veterinary officers were given authority to handle the existing machinery dealing with these products, they could eliminate much wastage and friction. He thought that the problem of tuberculosis in cows should be regarded in relation to the problem of animal disease as a whole, and urged the importance of preventive work among animals on a national scale. At the opening meeting a letter was read from the Prince of Wales in which he expressed his regret at being unable to attend the congress, and his appreciation, as an associate of the College of Veterinary Surgeons, of the work of the association. The letter concluded: "I think that in the control of disease, and especially those forms which are communicable from animals

to man, the veterinary surgeon has a role to fill equally as important as that of the medical scientist, and that every encouragement is therefore necessary. I am sure an interchange of veterinary opinions with those of practical producers cannot fail to be of benefit to the State generally."

THE Minister of Health in a circular (No. 921) to local authorities calls attention to the fact that the review on September 1st of Civil Service bonus is based on an average cost of living figure of 65, the bonus payable to officers whose salaries do not exceed £500 a year will, for the six months commencing on that date, be one fourteenth less than that payable during the preceding six months. In the case of salaries over £500 a year the bonus will still be subject to the special arrangements indicated in previous circulars. It is pointed out that in view of the decrease in the Civil Service bonus, it follows that the range within which bonus may be paid by local authorities to those of their officers who are remunerated is subject to the Minister's sanction is correspondingly reduced. Officers whose rate of remuneration for non manual employment falls to or below £250 a year as a result of the decrease in the bonus will become liable to compulsory insurance.

THE Joint Advisory Committee on River Pollution appointed by the Minister of Health and the Minister of Agriculture and Fisheries has issued its first report, dealing mainly with the legal and administrative aspects of the question, and containing a brief survey of the relative legislation. Attention is drawn to the fact that under the law as it stands at present the Minister of Health on the application of any county or county borough council through whose jurisdiction a river passes may set up a rivers board to control the whole length of the river and its tributaries so far as it is subject to the Rivers Pollution Prevention Act. The establishment of rivers boards would, it is suggested, be the first step towards the improvement of the condition of many rivers. Among the members of the committee is Dr. H. Maclean Wilson, Chief Inspector of the West Riding of Yorkshire Rivers Board. The report is published by H.M. Stationery Office at the price of 2d net.

THE report for the quarter ended June 30th of the Home Service Ambulance Committee of the Order of St. John and the British Red Cross Society again refers to the extensive use made of the committee's vehicles in the transport of casualties due to road accidents. While there has been no diminution in the number of traffic accidents recorded the establishment of first aid stations on the roads has minimized the effects. The task of the hospitals, it is claimed, has been lightened by the fact that an increasing number of patients brought in have already received skilled attention and have been carried in ambulances instead of being subjected to unskilful handling. Great difficulty has been experienced, especially in connexion with road accidents, in obtaining payment for the use of ambulances. The report suggests that motorists coming from London or other large towns where services are maintained by the municipalities do not realize that most of the ambulances in the country depend for upkeep on the moderate charges made for their use, supplemented by local voluntary subscriptions.

THE eighth Congress of the Society for the Study of Diseases of Digestion and Metabolism will be held in the Colonial Institute at Amsterdam from September 12th to 14th, when the following papers, among others, will be read: physiology and pathology of hunger, by Professor Morgulis of Omaha, the theory of the action of insulin in diabetes, by Professor Schurr of Vienna, treatment of diabetes with food poor in fat, by Professor Porjes, relation between diseases of the intestine and blood, by Professors Morawitz of Leipzig and Nordmann of Berlin, relations between diseases of the liver and blood, by Professor Schottmüller of Hamburg, and prevention of diagnostic and therapeutic errors in alimentary diseases, by Professors von Bergmann and Kuttner of Berlin and von Haberer of Düsseldorf. Further information can be obtained from the general secretary, Professor R. von den Velden, Bambergerstrasse, 40, Berlin, W. 30.

THE ninetieth Congress of the Society of German Natural Science and Medicine will be held in the Zoological Garden at Hamburg from September 15th to 22nd. The medical programme is a very full one, all specialties being represented. The subscription for members of the society is 20 marks and for others 25 marks.

THE twenty-eighth Congress of the French Association of Otolaryngology will be held in Paris under the presidency of Dr. Iselin, on October 9th, when there will be a discussion on strictures of the larynx, introduced by Professor Duvergey of Bordeaux. Further information can be obtained from Dr. O. Pastreau, 13 Avenue de Villars, Paris VII.

M. LOUCHEUR has been nominated Minister of Hygiene in succession to M. André Fallières, who recently resigned.

Letters, Notes, and Answers.

QUERIES AND ANSWERS

CHRONIC CYSTITIS

MR. G. B. RICHARDSON, M.B. (Edinburgh) writes: In answer to N.B.'s query (August 25th p. 382) I would say that in the absence of definite evidence—for example, negative Wassermann reaction—of causation the condition be regarded as syphilitic and that an intravenous injection of 0.45 gram of novarsenobillon be tried followed by a dozen weekly 1 ccm intramuscular injections of grey oil. Would it be objectionable to a short course of mercury to anyone infected by the spirochaete or not? It is an excellent tonic.

VAGINISMUS

"C.A." writes: I have a very obstinate case of vaginismus to deal with. The patient is a young woman of 23 married about two years and so far coitus has been absolutely impossible. She has seen a consultant surgeon who agrees with me that there is no local abnormality whatever. The vagina has twice been stretched under general anaesthesia without result. Any attempt at examination per vaginam has been impossible until anaesthesia was used. The surgical extent Cocaine suppositories were suggested but it was impossible to insert one. Can any of your correspondents who may have had experience of similar cases suggest any method of dealing with such a condition? Pregnancy would probably cure it, but it is difficult to see how this could be brought about.

MOUTH BREATHING

"SCHOOL MEDICAL OFFICER" writes: I should like advice in the cure of a child—a girl of 7½ years—who is a mouth breather. Is there any apparatus which will cure this bad habit? The child is of full intelligence, her adenoids were removed at the age of 3½ years for mouth breathing without success and at 6½ years the nasopharynx was scraped again and tonsils which were large dissected out but mouth breathing persists. The palate is high, the mandible V shaped and the teeth are getting crowded and lack symmetry. There is no nasal obstruction though the nares are small. Breathing exercises have been tried. I can get no help from any of the books I have read.

INCOME TAX

Replacement of Motor Cycle Use of Residence

"R.R.R." bought a motor cycle chiefly for work in 1921 for £120. In 1925 a car was bought and the cycle was used occasionally. In 1926 it was not used (not even licensed) and in 1927 it was sold for £10. The Inspector of Taxes declines to make any allowance for replacement. The house comprises eight rooms, three are on the ground floor one of which is used entirely for work and the other as a combined waiting room and dining room. He has been allowed one half of the rent and rates as for professional use but the Inspector now proposes to allow one third only.

"*." (1) It is clear that the car was, in fact bought and used in replacement of the cycle. We agree that no allowance can be given as in the year 1925 but are clearly of opinion that an allowance should be made as an expense of 1927 in the amount of (£120-£10=) £110 less any proportion referable to private use. (2) The question with regard to the house may be arguable. "R.R.R." might usefully consider whether the balance applicable to private use—one-half or two-thirds—represents an

amount reasonable for the private accommodation retained and might perhaps point out to the inspector that some portion of the non professional part of the house is used by the maid, who (presumably) devotes time to keeping the consulting room clean, attending to callers, etc. so that the two rooms downstairs are not the only ones affected

Deed of Partnership

"A H F" took a partner as from September 1927. He has supplied the inspector of taxes with certified accounts for the practice, and his accountant has now been asked a question which he can answer only from the deed of partnership. Can "A H F" successfully refuse to produce the deed for perusal by his accountant, and presumably, the inspector of taxes?

* * It should, perhaps, be remembered that the amount of tax payable by the firm is usually affected by the basis of division of the total earnings, and where that basis is complicated, or where the existence of a legal partnership may be in doubt, it is, we understand, not uncommon for the deed to be produced as evidence. The inspector of taxes however, has no legal right to demand its production. As "A H F" evidently feels strongly on the matter, he might inform his accountant that he is quite prepared to supply any information that may be relevant as to the terms of division of the firm's earnings, but regards the deed as a private matter between his partner and himself and does not propose to produce it unless it is formally required by the Commissioners in process of appeal.

Replacement of Car

"K D" bought a car in 1923, price £355 and in 1927 bought another for £245, retaining the old car for family and holiday purposes. What can he claim?

* * We think that "K D" can properly claim that his newer car has been replaced, and can treat as a professional expense of the year 1927—thereby affecting his income tax liability for 1928-29—£245 less the sale value of the old car as at the date it was last used for professional purposes. But we have known cases where the authorities have objected to make such an allowance until the old car has been actually sold and ceased to be available for professional purposes—for example, in the event of the newer car being out of order.

LETTERS, NOTES, ETC

TRAINING FOR THE D P H

DR T N KEITNACK (honorary secretary of the Royal Institute of Public Health) writes. The attention of my council has been drawn to a paragraph on page 416 in your Educational Number of September last dealing with the training of candidates for the Diploma in Public Health in London. In this paragraph you state by inference that the Royal Institute of Public Health will cease its training in this respect in October 1929. Will you allow me to say that there is no foundation for such a statement, but on the contrary it is the council's full intention to carry on the successful work which they have done in this direction for many years past. The council having obtained statutory provisions for the registration of the Diploma in Public Health by the General Medical Council, the subsequent legislation by which medical officers of health were required to possess such a diploma, and the curriculum of study for such from the General Medical Council by which uniformity in the value of the qualification was obtained determined in view of the inadequacy of the training in London for complying with the curriculum to establish laboratories, both bacteriological and chemical and provide the necessary training in other respects for such candidates. It is therefore most unlikely in any respect that they will abandon the useful and pioneer work which they have successfully undertaken for the past forty years.

A MODIFICATION OF THE LEISHMAN STAINING METHOD

MAJOR J C CHURCHBURY, I M S writes. The following is not suggested as an improvement on the original Leishman technique but as a "field method" for places where pure distilled water free from CO₂ is difficult to obtain. I publish it by the permission of the Director of Medical Services, India.

(1) Select an inch of the most homogeneous portion of the blood film. (2) Draw a perpendicular boundary line on either side with a grease pencil or better with a piece of ordinary candle, which is less expensive. (3) Pour as much freshly prepared Leishman stain as will cover the enclosed space and let it dry on the slide, preferably in the air or over a gentle distant flame. (4) Holding the slide with a pair of dressing forceps, dip it into methylated spirit kept in a wide-mouthed bottle always well corked and opened only at the time of use. Shake it well in the spirit until the film looks shining grayish blue. Too much decolorization will not entail retaining, for plunk. Too much decolorization because even if the white blood corpuscles malarial parasites retain some of their characteristic too little decolorization may entail a residual deposit. (5) Wash in a jet of tap water. (6) Blot immediately dry and mount. If sediment is still present repeat (4), (5), and (6).

Perfectly clean homogeneously stained fields show malarial parasites in bold relief even in their earliest stages of division. The nuclei of the white blood corpuscles are stained deep violet and the neutro base and acidophilic granules are beautifully shown. Many hundred slides have been stained by this method since October, 1927, when I first tried it, I have not used distilled water since. I have further observed that methylated spirit used for decolorization does not lose its fuel capacity. It can be used for lighting primus stoves and burning in spirit lamps. More than two hundred 1 in x 1 1/2 in films can be effectively decolorized by dipping and shaking them in four ounces of methylated spirit until it loses its effective decolorizing potency but retains its fuel property intact. The colour of the stained film will depend on the degree of purity of the methylated spirit which should be of neutral reaction. The staining results are as follows: red blood cells—shades of greyish pink nuclei—deep violet or shades of violet, acidophilic granules—red basophilic granules—deep violet, neutrophilic granules—lilac blood platelets—violet, malarial parasites—shades of blue, chromatin—ruby red.

BLOOD FILM EXAMINATION IN GENERAL PRACTICE

MR A J FAIRLIE CLARKE (Malvern) writes. A rough blood film, quickly made and examined, is often of value to the general practitioner in recognizing pneumonia, appendicitis and other conditions, and may help him to diagnose doubtful cases such as whooping cough or to differentiate bacillary and coccidial infection. The following technique provides an efficient rough clinical method. A saturated solution, in tap water, is made of corrosive sublimate. The dry smears are soaked in this for ten minutes or longer and then well washed under the tap. The fixer the blood to the glass. A teaspoonful of commercial methylene blue is put in a 4 oz bottle which is filled up with water from the tap. This stain is filtered direct on to the slide on which it remains for about ten minutes. (A porcelain drenching dish makes a convenient sink and a small ornament pot is a suitable stand for the slide.) The slide is next gently washed in tap water till most of the colour has gone, it is then blotted and dried by waving in the air. For examination a dry 1/6 in lens is used with a small substage diaphragm, closing down the diaphragm is essential. Examining the slide in air simplifies technique and allows eosinophilic to be detected without counterstaining, these cells are clearly distinguishable by their mulberry contour and refractile granules but are not so recognizable when the film is mounted in balsam. By this method the nuclei of the polymorphs show up well and I believe that it is possible to make a reasonably accurate Arnetti or polynuclear count another very valuable aid to the general practitioner. Finally the discarded slide is boiled for a minute or two in a small vessel containing a thick mixture of soap and water rinsed in hot water and dried ready to serve again. Two useful accessories are a spreader for the blood smear made from a microscope slide 1/16 in being ground away (on a flat stone or emery wheel) at each corner of one end of this slide at an angle of 45 degrees and the truncated angles thus formed being ground to steep knife edges while the other accessory is a microscope lamp made by cutting a round window in a cylindrical tin and suspending a frosted electric bulb from the lid.

PIREXIA ASSOCIATED WITH B. PYOCYANUS

DR R T VERN HODGE (Woodford Green, Essex) writes. In view of the present prevalence of paratyphoid fever I think it worth while to report the case of a young man aged 21, taken ill on July 1st with headache and extreme lethargy. Three days later both symptoms persisted, the temperature ranged from 101° in the morning, to 103° F at night and the pulse was slow. The fever continued for three weeks and then fell gradually with diminishing evening rises the pulse remained between 72 and 80 the chart resembling that of a typhoid infection. At the end of the first week the throat became painful but thrush fungus alone was recovered by swabbing. Widal tests were negative on the twelfth and thirteenth days. At the end of the third week a good growth of *B. pyocyaneus* was recovered from the stools in addition to *B. coli* and intestinal streptococci. I should be glad to have information about any similar conditions produced by this organism.

A REQUEST FOR BILBERRIES AND MULBERRIES

DR R D LAWRENCE (King's College Hospital S.E.5) writes. May I through your agency ask the help of doctors or their patients in a small matter? We have been analysing the carbohydrate content of fruits and vegetables and are unable to complete a few which are not obtainable in the London shops. We have failed to secure bilberries and mulberries and any information which would enable us to obtain these would be very helpful. Of course a gift of small amounts (say 1/2 lb) from a few sources would be still more gratefully received.

VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals will be found at pages 35, 36, 37, 40, 41 and 42 of our advertisement columns and advertisements as to partnerships, assistantships and locum tenencies at pages 38 and 39. A short summary of vacant posts notified in the advertisement columns appears in the Supplement at page 131.

Remarks

OF

ACUTE CONDITIONS IN THE LOWER ABDOMEN OF THE FEMALE

BY

W. W. CHIPMAN, M.D., I.R.C.S.P.,
Professor of Gynaecology and Obstetrics, McGill University,
Montreal

Two general considerations

1 The genital tract in the female is a hollow cylinder, bifurcate above, which communicates directly between the skin surface and the peritoneal cavity. A direct channel, or avenue of communication between a contaminated skin surface and this mesothelial space¹ (Victor Bonney)

And this genital tract is subject to many vicissitudes. There are the traumata of menstruation, of childbirth, and abortion, and the dangers associated with venereal disease. It is an imperfect world. Hence in the female the frequency of acute infections of the lower abdomen.

2 The peritoneal cavity is one of the three large enclosed chambers of the body—it is the largest of the three the largest lymphatic space. Its absorptive surface is immense, compared either with the pleura or the subdural space. Hence the danger of an acute infection of this large space. The peritoneal cavity—an organismal Valhalla—a perfect incubation chamber.

These acute conditions are sometimes grouped together under the term, "The acute abdomen," "The emergency abdomen," or "The abdominal emergency." The point of the emergency concerns both the patient and the surgeon, and any given individual has only one abdomen. To open or not to open—that is the question, a decision of entimes of very grave importance.

I need not tell you that the opening of the abdomen should never be lightly or carelessly undertaken. I object to the term of "giving the patient the benefit of an exploration." "Open and see" is a foolish hehest. If too often done this may be interpreted as "condemning the patient to an added injury." In surgery we must remember the three "C's"—caution, care, as well as cutting. You will also agree that before any abdominal operation is undertaken a vaginal examination, a rectal examination, or both, should invariably be made.

In general terms, these acute conditions may be grouped as follows:

- 1 Haemorrhage, a concealed haemorrhage
- 2 Acute infections, usually of the uterus, the Fallopian tubes or the appendix
- 3 Perforation of the bowel or other hollow viscus—perforation or rupture
- 4 An acute bowel obstruction
- 5 Strangulation of any organ or neoplasm
- 6 The passage of a ureteral stone
- 7 A uterine abortion, spasmodic dysmenorrhoea, or even a bladder retention

For the gynaecologist the most common of these are a ruptured ectopic pregnancy, an acute appendicitis or salpingitis, a uterine infection, strangulation, thrombosis, or an ovarian cyst, or uterine fibroid with a twisted pedicle.

Speaking in a general way for all these conditions, some of them are at once recognizable—his who runs may read—while others require a most painstaking differentiation.

May I first make two pleas of a preliminary character? The first concerns the wisdom of a careful case-history, for in many of these conditions the previous history, or the story of the onset, may afford the clue. Sir James Mackenzie pointed out that in difficult cases the diagnosis frequently depends more upon an exact history than even upon a careful examination. My second plea is always to pass a catheter, and to examine the resulting urine.

I shall now discuss in a general way the various signs and symptoms of these acute conditions.

Pain is always the outstanding symptom. It may well

¹ Paper read in the Section of Obstetrics and Gynaecology at the Annual Meeting of the British Medical Association, Cardiff, 1929.

be defined as Nature's expostulation to an injury, and its function is a protective one. La Rocheffoucauld has told us that pain is the greatest liar in the world, but it is wise not always to believe this. At times it is a liar, and so for the matter of that are all men, and a few women, but I believe it is wise to take the following advice: "Never open the abdomen for pain only"—for pain only and with no accompanying signs or symptoms.

The most important sign, perhaps, is the face—the abdominal face—the facial expression, and this never lies. So often it is the anxious peritoneal face, apprehensive. In haemorrhage it is pallid, often waxy, and the mucocutaneous line of the lip is unduly sharp and pronounced. There is the grey ashen face of shock, and the flushed or cyanotic face of a severe toxæmia. The severity of the lesion can often in this way be immediately inferred.

And there is the attitude of the patient, her decubitus and her mobility. If the lesion be acute and intraperitoneal, the patient lies invariably upon her back, and with her knees flexed. Any movement is a torture. On the other hand, if the patient moves readily, and turns easily on her side, there is no grave lesion within the abdomen. I have often found this test of asking the patient to turn over on her side of great service.

So far, you will observe, I have not mentioned either the temperature or the pulse rate. I shall refer to them later in their special place. Let us now consider the three commonest of these lower abdominal conditions. These are haemorrhage, acute infections of the appendix or Fallopian tube, and a strangulation or thrombosis of a pelvic organ or neoplasm.

1 Haemorrhage

The first of these is haemorrhage. The common site, of course, is a ruptured tubal pregnancy. A severe haemorrhage may arise, however, from other situations—for example, from a ruptured Graafian follicle. Three years ago Primrose of Toronto reported six such cases. I have met one in my own practice, and there was a large loss of blood. Again, a varicocele may rupture, and a uterus ruptured during labour, or perforated even by a sound or curette, may lead to a severe intraperitoneal haemorrhage. The history here is all-important.

Usually the condition is that of ectopic pregnancy. As you know, the history of the pregnancy, the amenorrhoea, is often indefinite. Rupture occurs usually between the seventh and the twelfth week, and this rupture may be large or small. The dangerous situations are the isthmus and the cornu of the uterus. If large, the haemorrhage is usually severe—the cataclysmic ease with pallor, subnormal temperature, rapid and thready pulse, air-hunger, cold and clammy extremities. The abdomen is tumid and tender, frequently tympanitic, for the bowel floats, the blood has a high specific gravity. The pouch of Douglas may be full and depressed, and a feeling of crepitation may be present as the finger breaks the blood clot. There is frequently the history of a dagger-like thrust of pain, with immediate faintness or collapse. A uterine trickle of blood is often manifest, together with rectal tenesmus, and some bladder stranguary. In these severe cases the diagnosis is easy, and does not require the taking of a haemoglobin index. The abdomen should be opened at once, and venous transfusion, of citrated blood or a glucose saline, carried out.

It is well to remember that if such a patient survive and be not seen till the fourth or fifth day she may present all the signs and symptoms of a widespread peritonitis—namely, fever, a rapid pulse, a distended abdomen with paralytic ileus, regurgitant vomiting, with a marked leucocytosis—the picture of late bowel obstruction.

In a so-called chronic case—the "leakers"—while the diagnosis is less urgent, it is sometimes more difficult to make. There is the history of repeated attacks of sharp, lancinating pain in the lower abdomen, an interval of twenty-four or forty-eight hours, or even some days, between them, slight uterine haemorrhage, no marked fever or great disturbance of pulse rate, a lateral mass on one or other side of the uterus, increasing rapidly in size. Mark such a case. If a decidua is shed from the uterus—this occurs in only about 20 per cent of the cases—the diagnosis is clear.

There is in these cases a degree of anaemia, there is often a marked leucocytosis (De Quervain contends that a leucocytosis of 20,000, where signs are slight, points to a haemorrhage rather than to an inflammation). A haemoglobin index is of small value. Two years ago the hope was expressed that a low and falling index would reveal a concealed haemorrhage. Unfortunately, this is not so.

We rely in these cases upon the history—the recurrent attacks of pain, the uterine bleeding and mass, at first lateral to the uterus, which increases rapidly in size. It is always well to bear that in mind. If in doubt, an exploratory colpotomy is the indication, and it settles the matter. If blood is found, the abdomen should be opened from above and the tubal sac removed.

2 Acute Infection of Appendix or Fallopian Tube

The second common condition is an acute infection—an infection of either the vermiform appendix or the Fallopian tube. The distinction between these two infections is all-important, for an inflamed appendix should be at once removed, certainly within the first twenty-four hours, while to open the abdomen for an acute salpingitis is nothing short of a disaster.

The inflamed appendix we all know, with its more or less definite syndrome, outlined first by Reginald Fitz, and its surgical treatment indicated by Charles McBurney of New York. Professor Wilkie of Edinburgh emphasizes an important pathological and clinical distinction. He says

‘There are two main types of acute appendicitis: (a) the one infective, an organismal invasion of the lymphoid tissue of the inflammatory type, here there is pain more or less continuous but not severe fever, increased pulse rate, localized tenderness, and a marked leucocytosis; and (b) the obstructive type, faecal concretions often present blocking of the circulation and sudden gangrene, and perforation. Here the pain is intense and spasmodic, the fever is slight, the pulse is often rapid—the abdominal faeces—and no great increase in leucocyte count.’

These are his two main divisions, and I think they are well founded.

The common infection of the Fallopian tube we are all familiar with. It is really a mixed infection, an acute exacerbation of a chronic condition. The chronic infection is a gonorrhoeal one, rarely tuberculous, and the acute malfeasit synergism is frequently due to the colon bacillus.

It is the distinction between these two acute conditions, the one of the vermiform appendix and the other of the Fallopian tube, that sometimes taxes our clinical acumen to the utmost. How shall we proceed to such a distinction? It is, I admit, an old story, but one that in our daily practice is ever new.

In a general way it may be said that in acute salpingitis the patient does not appear so ill, the temperature is often high, it is true, usually higher than in appendicitis, but the pulse rate is not correspondingly disturbed. The face is often flushed but not to the same degree anxious or apprehensive. The function of the bowel is not so greatly disturbed, nausea and vomiting are not a feature though there may be considerable distension, abdominal tenderness and rigidity are more diffuse and widespread. All this in a general way, the general rule if you like, where there are bound to be exceptions.

The history of the case—of the onset, or of previous attacks, a previous complicated puerperium, a one-child sterility, with depraved menstrual habit—may afford a clue. And then in our examination we always look for signs of a gonorrhoeal infection. As I have said, it is an imperfect world. First, the signs at the vulvo-vaginal outlet, the chronic urethritis, with the pointing and oedematous tubules of Skene, the maculae gonorrhoeae at the opening of the Bartholinian duct—these are all signs that a gonorrhoeal infection has passed that way.

If the infection be a Noeggerath's infection—a chronic gleet in the male—there will only be the chronic cervical catarrh and the immobility of the uterus—the uterus fixed in situ, as it were, and often with no definite appendage mass. Yet at this time the appendages are slightly enlarged and very sensitive, and the mere movement of the cervix uteri elicits severe pain.

With such a finding the diagnosis is an acute exacerbation of a chronic salpingitis, with a spreading peritonitis, and the indication is—*above all things do not operate*.

The situation in these cases was well summed up some years ago by one of our able southern surgeons, when he said, “In a gonorrhoeal salpingitis, never operate in the acute stage, wait till the cold stage, and clear them out.” Never operate till you are compelled.

In contradistinction to this clinical picture I think it is wise for us to keep in mind a typical attack of appendicitis. The history helps us here. There may have been previous attacks, but—

The pain is first felt above the umbilicus or in the epigastric region, it soon determines itself in the right lower quadrant. There is anorexia, or nausea, or even vomiting. There is tenderness over McBurney's point, which we remember is the base of the mesentery of the appendix—a lymphangitis. There is also some muscular spasm or rigidity of the right rectus or oblique muscles, with fever or quickened pulse rate, often not specially pronounced. There is a moderate leucocytosis—ten to twelve thousand—with polymorphs predominating. If the inflamed appendix be near the brim of the pelvis a vaginal or a rectal examination shows a marked tenderness in the neighbourhood of the right sacro-iliac joint.

Such is a typical clinical picture of a catarrhal appendicitis. We can see at once how it differs from an acute salpingitis. When in doubt between the two watch and wait—hour by hour, not day by day.

3 Thrombosis, Gangrenous Organ or Neoplasm

Here the lesion is a definite venous thrombosis, or a twist in a pedicle. The common neoplasms that suffer this pathology are ovarian cysts of medium size, or a fibromyoma of the uterus, pediculated or intramural. Frequently the patient has been aware of the presence of the neoplasm. The pain is severe and colic-like, short in duration, and the tenderness is at first localized to the tumour surface, there is slight disturbance of temperature or pulse rate.

A careful examination discovers the neoplasm. If the thrombosis be extensive or the strangulation severe, and the patient be seen late, there are all the signs of a superadded peritonitis, the result of a colour infection. These three conditions mark the common acute lesions of the lower abdomen.

May I add here a word of warning in respect of pneumonia?—a pneumococcal infection, which may spread below the diaphragm and simulate even an appendicitis. My warning consists in this—a careful history of the onset. If a rigor has occurred, a chill, it is probably not appendicitis. In a series of 85 cases of appendicitis a chill was recorded but three times, so, if there is a chill at the onset, watch the alae nasi (count the respirations), think of pneumonia, and make a leucocyte count. If the leucocyte count be over 15,000 in the first twenty-four hours the condition is likely to be pneumonia and not appendicitis.

A word or two concerning bowel obstruction—an obstruction of the lower bowel. I need not remind you to examine all hernial orifices. An intussusception is common only in the young or adolescent, and soon gives rise to a typical ileo-caecal tumour and the characteristic bloody-mucous bowel discharge. A volvulus occurs rather in the old, a rare left-sided lesion, which can usually be felt by bimanual examination.

The obstruction causes colic, with quiet intervals, constipation, of course, and, later, the antiperistalsis, may result in vomiting. A diverticulitis occurs usually in the pelvic or iliac colon, and diarrhoea is a frequent concomitant—diarrhoea and fever.

A stone in the ureter or in the pelvis of the kidney may cause abdominal distension and vomiting, and not a few abdomens have been mistakenly violated. The onset of the pain, its distribution into the urethra or down the leg, frequent micturition, and blood in the urine may possibly identify it. If in doubt, an x-ray picture should be taken.

A good surgeon must first be a good physician—a mind broadly trained, and the hand narrowly. The function of the good surgeon is to diminish surgery in the world to-day.

THE FALLING BIRTH RATE *

I—THE BIOLOGICAL ASPECT

I. A. E. CRAW, M.D., Ph.D.,

Animal Breeding Research Department University of Edinburgh

THE birth rate of this country has fallen and is still falling. That this is so is a matter of very grave concern to those who choose to envisage the overwhelming of our prized culture by hordes of barbarians of this or of that particular line, but all equally and amazingly fertile. To the biologist, however, there is nothing remarkable and nothing necessarily ominous in this decline. Had the conclusions which have emerged from the work of Pearl and his associates, and of Elton and others, been known at the time when the birth rate was soaring, this present fall would have been foreseen and accurately predicted. To the biologist a falling birth rate is nothing but the sign of the approaching end, not of a people or of a culture, but merely of a population growth-cycle.

All living things, be they pumpkins or peoples, exhibit in common the quality of growth. The growth of every living thing—an individual animal or plant, unicellular or multicellular, a congregation of cells or of multicellular individuals—follows the same scientific law. In the absence of appropriate external conditions there is no growth. Growth, due to the production of new living material or of new individuals, is encouraged, permitted, embarrassed, or prevented by conditions incident to development. The beginning of an individual, or of a congregation of living units, is small, but, in virtue of this inherent developmental impulse to grow, increase in size of the whole, and in size and number of its component parts, occurs.

The law of population growth, as enunciated by Pearl, states that the population at first grows slowly but gains impetus as it proceeds, passing gradually into a stage of rapid growth, which finally reaches a maximum rapidly, and that after this stage of most rapid growth is passed the population increases ever more and more slowly until, finally, there is no more perceptible growth at all. Such is the history of a single population growth-cycle. Stated somewhat differently, the law postulates that, within one and the same cycle and in a spatially limited area, growth in the first half of the cycle starts slowly, but the actual increment per unit of time increases steadily until the mid point of the cycle is reached. After that point the increment per unit of time becomes steadily smaller until the end of the cycle. In a spatially limited area the amount of increase which occurs in any particular unit of time at any part of the single cycle of growth is proportional to (a) the absolute size already attained at the beginning of the unit interval under consideration, and (b) the amount of unused or unexpended actual and potential resources for the support of growth in the given area. (In the case of human populations (b) includes such things as the amount of agricultural land still uncultivated or imperfectly cultivated, and new discoveries relating to production, manufacture, and distribution.)

If the birth rate of a population living in a spatially limited area remained constantly higher than the death rate, growth would continue according to an exponential curve to infinity, and no pause, and no fall, would be discernible. The result would be an ever-increasing density of population, leading ultimately to complete saturation. If, at the same time, the increase in available food did not parallel the increase in the needs for it, there would be ever-increasing insufficiency, leading ultimately to famine. The problems of increasing density and deficient food supply could be solved temporarily, and from time to time, by migration into less favourable regions, and by modifying the dietary. But it may be assumed that to both of these expediences there must be limits, and that ultimately, if harmony between container and contents is to be preserved or restored, the population must needs become stationary or reduced. The quart in the pint pot

must overflow, and a part be spilt and lost. This reduction in population could be achieved by removing the surplus or by reducing the rate of growth.

The first method of population reduction is the catastrophic, and is exemplified by the work of Elton on wild rabbit, field mouse, and lemming populations, and of McKeendrick on human populations. It would seem to be the case that as soon as population density reaches a certain level, epidemics, which otherwise would fade out, race through the whole population. The establishment of a harmonious relation between the density of a population and the habitat, by the removal by death of a proportion of the individuals, is to be observed in the case of the litters of polytocous mammals. Corner, Hammond, and others have shown that in the pig, for example, there is a considerable reduction in the number of the embryos resulting from conception, and an orderly spacing of those that remain, the actual size of the litter being determined in great part by the abundance and quality of the food supply. The instruments that play their parts in this catastrophic increasing of the death rate are war, pestilence, and famine.

The second method, that of reducing the birth rate, is revealed in the work of Pearl on *Drosophila*, where the primary cause limiting population growth is a fall of fecundity and fertility with increasing density. In this it is seen that the process is relatively gentle and orderly. It would seem that the conditions incident to overcrowding provoke a reaction on the part of the living organism which takes the form of a depressed fecundity. In the case of the mouse, it is the male which first reacts in this way to overcrowding. In the case of human populations this passive response to environmental discomfort can be replaced by a deliberate and conscious control of the reproductive rate (birth control). The end-result in all cases is the same, the rate of population growth is checked. It is for human societies to compare the different methods and to decide which shall operate—the catastrophe or the orderly, the overwhelming or the controlled. Is it not the case that if there is food scarcity and overcrowding in a spatially limited area then, by this method or by that, there follows a reduction in the population, and a re-establishment of the harmony that must exist between the life-supporting capacity of the area and the sum of the living? It may be that mankind can adapt itself so that it will be able to flourish in circumstances which now are impossible. For the present, however, a generous amount and quality of food, and a certain amount of elbow-room, are prerequisites to normal development.

Mankind can not only adapt itself to a changing environment, but can also modify the conditions of its habitat. Every advance in the application of knowledge which amplifies man's power to derive more fully from his physical environment things conducive to his material welfare increases the potentialities for population growth in a given area. Any discovery relating to the production, manufacture, or distribution of food may quickly be followed by changes in habits, and then either the upper limiting value of the population attainable in the cycle of growth then current is moved up, or else a new cycle of growth starts from a base line of the population already attained at the end of the previous cycle. That which an implant of anterior pituitary can do for the individual, industrialism can do for an agricultural population.

A rising birth rate heralds an extension of the conquest by man over his environment or over himself, a falling birth rate is an indication that mankind in a particular area is temporarily or permanently imprisoned. Man, like certain other animals, does not breed freely in captivity, even though this is picturesque and apparently comfortable.

The birth rate is falling now because this is the end of a population growth-cycle, and it will not rise again until those factors which are at present overriding the inherent tendency to increase are recognized and removed. When this has been done a new growth-cycle will be initiated and the birth rate will rise.

Most of these factors are, without doubt, social and economic, but, whatever they may be, they must produce

* A discussion in the Section of Medical Sociology at the Annual Meeting of the British Medical Association Cardiff 1928.

then effects because they condition the action of the forces of natality, mortality, and migration. The birth rate is the reflection of the operation of those agencies which raise or reduce fecundity, render fertilization more or less sure, and which do not, or do, interfere with the development of the products of conception.

Fecundity, the power of elaborating functional gametes, is affected by inborn and environmental factors which determine (1) the number of ova available for fertilization, (2) the frequency of ovulation, (3) the functional ability of the gametes.

Fertilization, the fusion of the gametes to form the zygote, is influenced by inborn and environmental factors which affect (1) sexual congress, (2) the actual union of ovum and sperm.

Pregnancy is influenced by inborn and environmental factors which affect the processes of development of the embryo and foetus.

Difficult as it is to disentangle the environmental factors, which profoundly influence the reproductive functioning of the individual, from the inborn, an effort to do this must be made, even though the result may be useful only in serving to emphasize the depth of our present ignorance and the urgency of the need for ardent experimentation. Much of what is known has emerged from the study of experimental material other than man, and this fact must be remembered in any discussion concerning human populations. It is not safe to transfer, by simple inference, conclusions derived from the study of less complex forms to the case of man, it has to be shown that that which holds for one form holds also for another. Moreover, even though the same phenomena are presented by two different forms, it does not necessarily follow that the causes have been the same in the two cases. But natality and mortality are not the peculiar possessions of humanity, and, therefore, it is highly possible that the conclusions reached in experimentations with mice, for example, may at least suggest lines of profitable inquiry into problems of human population.

Biological inquiry in the past has concerned itself mainly with problems that relate to the individual, the group has seldom been studied. It is established, however, that a congregation of individuals is biologically different from the sum total of the individuals comprising it, the whole in the organic world is something more than the sum of the parts. An intimate knowledge of a great number of individual bees could not explain the hive, a thorough understanding of the biology of the individual human subject does not comprehend the State with qualities and attributes peculiar to itself. But at long last the science of group-biology has come into being, and its contributions, though as yet but few, are important in themselves, and in that they point the way to a clearer understanding of the work that must be done before policies can be soundly based and brought into harmony with established biological fact.

The ability of a pair to beget offspring is conditioned by the ability of the individuals concerned to elaborate functional gametes. Though fecundity is influenced very directly by environmental agencies, including food (vitamins B and E, for example), yet it can be demonstrated that different races, stocks, and individuals are to be distinguished one from the other by true-breeding differences in fecundity. In the human subject the tendency to multiple births is faithfully transmitted through both male and female. This being the case, it follows that the birth rate of a population is affected by the proportion of "multiple birth" stocks present in that population. The King's Bounty is one method of making this true-breeding character socially worthy; the jokes of the music-hall are but modern versions of older taboos.

The reproductive rate of a pair, or of a community, is controlled by the frequency of the opportunities for effective fertilization. In a general way it may be accepted that the frequency of menstruation is an indication of the frequency of ovulation. Thus the reproductive rate is proportionately higher in those races, stocks, and families in which puberty is attained relatively early, menstruation is more frequent, the climacteric later, and the length of life greater. The relative time of onset of puberty is a true-

breeding character, so also are the relative time of onset of the climacteric, and longevity. It is possible that in the past the inherently longer-lived contributed disproportionately to the population, since the others were wiped out more quickly, and therefore had but few offspring, and that under modern conditions the latter live longer and transmit to their progeny this lowered fecundity. This would be a reasonable explanation of a lowered birth rate if it could be shown that there exists a high correlation between longevity and high reproductive rate. The frequency and intensity of menstruation, like all the other phenomena, are largely conditioned by environmental agencies, but, when all due allowances have been made for these, it still remains a fact that race can be distinguished from race, and stock from stock, by differences that are faithfully transmitted. In certain human females the *mittelschmerz*, the interval pain, may possibly be an indication of a secondary menstrual rhythm superimposed upon the main one, and it may be that such females ovulate more frequently.

Since the population has increased disproportionately to the accommodation and food supply, this country is now relatively overcrowded. There is a fundamental law by which the growth of a population is regulated by its own density. When the density reaches a certain point the death rate rises and the birth rate falls. Density applies not only to a country but also to its apartments. Lack of houses is an indication of a relative regional overpopulation, if, and when, the builders fail to keep pace with the babies, the birth rate will fall. The present housing shortage not only affects the birth rate indirectly through the marriage rate, but also directly through increasing density. How density provokes its results is not known, but the work of Pitt-Rivers perhaps suggests that sheer discouragement is enough to destroy a people. In the case of the vanishing peoples of the South Seas observed by him, coitus occurs, and there is no attempted contraception, yet the birth rate is steadily falling. The clash of cultures has made these peoples discontented and discouraged, and they are dying out. They cannot, or will not, adapt themselves to changing circumstances, and, therefore, they must perish.

There must be joyousness, eagerness, roominess for potential parents, or else the babies will not come. The birds when they mate build nests, but for human lovers the tenement is built by those who are ignorant of the relation that exists between population density and reproductive rate. The birth rate is falling because among other things this country is not fit for parents to live in, we await the coming of a new discovery, scientific or political, that will raise the level of the optimum density endured by mankind or increase and further democratize material prosperity.

The opportunities for fertilization are determined by the proportion of women of fertile age in the population, by the proportion of these who are married, and by the fertility of the marriages. The nature of the sex-ratio, the system of marriage, and the sexually selective catastrophic death rate of the late war condemn a great number of women to permanent yet undesired virginity. The sex-ratio cannot as yet be controlled. This is not the occasion for a discussion on the biological aspects of the prevailing marriage system, and the effects of the war are too manifest to require argument, but the fact that many women cannot become mothers cannot explain the falling birth rate. A high marriage rate associated with a low per-reproductive-woman birth rate can yield the same reproductive rate as can a low marriage rate associated with a high per-reproductive-married-woman birth rate. It would seem that in an inelastic habitat many marriages mean small families, whereas few marriages mean larger families. It is indeed probable that there is an inverse correlation between marriage rate and birth rate per reproductive married woman. Again, the controlling factor would seem to be density. Few marriages and larger families may yield a high reproductive rate, but it may be expected that among the offspring of relatively few couples there will be less variety, and variety surely is to be desired.

There can be no doubt that the present low birth rate is in part due to the incidence of sterile marriages. In certain cases it would seem that the ovum and the sperm

more as mutually antagonistic physico-chemically as are the blood serum and corpuscles of individuals belonging to different blood groups. There is no doubt that two individuals, mutually sterile, can yet be fruitful in other matings. But even the presence of mutually sterile couples in the population cannot account for the fact that the number of children per mutually fertile couple has also fallen. Perhaps the social and economic developments during recent times have permitted, or even encouraged, the survival of stocks which were, and are, relatively infertile, or which react more readily to the disharmonies attendant upon industrialism.

The peak of sexual activity, as established by the frequency of sexual intercourse, is about 29 in the male, while a woman's reproductive power drops sharply after 30. It follows therefore, that those who marry late tend to have fewer children. The relatively and highly fertile are such as reach full earning power early, and marry at a younger age. Prosperity implies plentiful food and comforts, and an adequate medical service and, therefore, a lowered death rate and a rising birth rate. But if such prosperity is associated with an unequal distribution there will be a differential fertility among the social grades created by this prosperity. Possibly Bernard Shaw's scheme of equal distribution would be followed by an equalized fertility rate throughout the community. If a large section of the community which is, socially, relatively unsuccessful, though by no means necessarily relatively unskilled in the biological sense, is left with no other mode of nervous release save that which excessive drinking and sexual over-indulgence can give then there will be a higher reproductive rate among these than among the community as a whole. Social advancement implies a lowered reproductive rate, for the reason that those who can, and do, advance socially are presented with a greater variety of modes of self-expression and of self-indulgence.

In one sense children are commodities subject to the law of supply and demand. There was a time when children could be regarded as commercial assets, but the Factory Acts have greatly depreciated their value as wage earners. One could assume that in these days when it would seem that everyone must be acquainted with methods of preventing fertilization, only those children are born whose coming is desired. Is not the fall in the birth rate due, in the main, to the spread of a deliberate and conscious limitation of fertility? It is undoubtedly the case that among the middle and upper social classes contraception is widely attempted. This being so the conclusion that these methods attain the end desired by those who employ them is inherently probable. But, unless it can be shown beyond all reasonable doubt that the methods employed are actually effectual, it cannot be accepted that birth control is largely responsible for the fall in the birth rate. It certainly has affected the marriage rate, in that a faith in contraceptive methods has caused this to rise. But such records as there are certainly seem to show that this faith is too often misplaced. Of course, birth control has undoubtedly prevented the birth of a great many individual babies, and it is probable that many of the methods now in vogue lead indirectly to later and permanent infertility. But it is very doubtful indeed if birth control has affected the population growth-curve—the crude birth rate. The fall in the birth rate has been too gentle, it has proceeded with evolutionary steadiness, and it has been universal. It would seem, therefore, that the fall must be the expression of some biological factors, and not due directly to some local social disturbance which produced repercussions throughout the world. Birth control, like migration, does not put waves into the curve of growth of a population already of a certain absolute size, it merely alters a population by altering the proportions of the different sections. It can be argued that the same total number of babies have been born as would have been born had birth control not been heard of, birth control has played its part no doubt, but may it not be that all that it has done has been to slam the doors of suburban houses and to open those of a slum? It would seem to be the case that conscious and deliberate limitation of fertility has been, and is, practised mainly by the

socially relatively successful—that is, by the inherently relatively infertile. If this is so, then it has prevented fewer conceptions than it would have done had it been employed by the socially relatively unsuccessful. The problem thus becomes that of determining the relative biological worthiness of the social grades. Is the present social structure one that encourages and rewards biological worthiness? And what is fitness? There is no reason to assume that, whatever this may be, it is linked with high-grade fecundity. The elephant is fit, and so also is the carwig, yet their reproductive rates are nightly different. Is the standard for humanity to be good physique, good brain, and low-grade fecundity? If so, then the ideal can be found abundantly among all social grades.

The suggestion that the relatively unfit are more abundant among the socially submerged is not necessarily true, for it must not be forgotten that it is far easier for a good man to climb out of the gutter than for a socially and biologically unworthy scion of an established family to descend to its depths. Many are those who float gaily in the mid-stream of social life, buoyed up, not by their own intrinsic worth, but by the efforts of their more worthy associates.

However, even though birth control may not have played any considerable part in the production of this fall in the birth rate, it would have been well for humanity had it been the only responsible agent, used intelligently by a people who knew what they did, and why they did it. All other methods are imposed upon a people, this is one that may deliberately and consciously be employed by a State to achieve harmony whilst new discoveries are awaited. At the present time it would seem that most, if not all, methods of birth control are too uncertain to allow any policy to be based upon their employment. A real control of fecundity and of fertility must soon be achieved if man, the rebel, is to consolidate the gains that he has won from Nature.

The course of pregnancy and parturition is affected by factors which disturb the harmonious and parallel development of the maternal organisms on the one hand and of the foetus on the other. It is not improbable that, if the rate of the development of the pregnant uterus becomes out of time with the rate of development of the foetus, abortion results. Sex-linked lethal factors can operate in this way, as can also genetic disharmonies in the time or rate of functioning of the endocrine glands. The birth rate of that race or stock in which such genetic factors exist must necessarily be affected.

Such, then, is my contribution to this discussion. I have tried to be provocative, I have incautiously stepped from the solid ground of fact to the uncertain terrain of opinion, but on my opinions I set no great store, none of them are precious to me. I trust that I have faithfully performed the duty that I undertook, that of exciting you to rob me of my point of view. I shall not mind if, in exchange, I get a better.

II—THE ECONOMIC ASPECT

BY

W. J. ROBERTS, M.A. Oxon

Professor of Economics and Political Science, University College of South Wales and Monmouth Cardiff

THERE has been a period in which certain propositions concerning population were widely considered to rank as well-established and most important theorems of economic science, and an economist who did not profess or accept them would at least be expected to discuss them and to give his reasons for rejecting them. Malthus, the propounder of these laws of population, as they were sometimes called, was believed to have enormously increased the range of historical facts which the economist could explain, and to have indicated and established conditions of human social life on earth which no economic thinker, who was not satisfied with building castles in the air, could long afford to ignore. It is well known that Malthus's treatment of population, which secured the assent of a long-continued tradition among the political economists of

many nations, also acquired a wider biological significance through suggesting to Charles Darwin certain lines of inquiry into the variation of species. Some of Malthus's main contentions appear to have been, in fact, biological propositions and not propositions to which economic inquiry, in any proper or limited sense, would have led him. This is assuredly of no importance in comparison with the truth of the contentions themselves, and I mention it here only because I shall presently have occasion to distinguish between propositions which are themselves economic and propositions which, however much it may concern the economist to take account of them, are not established by any method or inquiry which belongs specifically to economic science.

Economists continue to discuss the question of population, and most of the comprehensive treatises will be found to contain considerable sections devoted to this discussion. Recent inquiry by economists and sociologists into the theory of population is much more critical and tentative than the argument found, for example, in Mill's *Principles of Political Economy*, a work which I mention especially because it was one of the last general treatises published in this country to present the old doctrine of population in a readable and overwhelmingly persuasive form. I cannot claim that the science of economics now offers an orthodox or generally accepted doctrine of population, with the suggestion that the intelligent student can, once he has understood it, set about "applying" it with confidence to the actual situations which confront him. What can be claimed on behalf of our contemporaries is that they have access to a much wider range of facts than their predecessors who so confidently propounded a law of population, that, in particular, statistical data are much ampler and statistical methods much more refined, and that economists and kindred inquirers are apt to discuss the problems of population responsibly, and in view of important social issues. But a simple and definite theory or law of population no longer holds the field.

"Restriction of births" occupied a prominent place in the presentation of the older theories, and the notion has accordingly been familiar to economists since the first publication of Malthus's work. His fundamental proposition was that the population tended naturally, by the birth of new members, to press against the limits of subsistence or of food. The excessive population necessarily perished, though not in all cases directly of starvation, misery, pestilence, war, and other such "positive checks" diminished the number of the population, and thus anticipated the work of starvation, selecting, we may notice, victims who would not necessarily all have died of starvation, but, at all events, giving a better chance of livelihood to the survivors. The operation of such causes as starvation, war, and pestilence in reducing the population might, it was argued, be replaced, with great advantage to human well-being, by prudential checks on multiplication, as, for example, later marriage, marriage only when future livelihood was assured, and so on. The artificial prevention of conception was advocated by later writers and agitators as a suitable prudential check, but often guardedly, and subject to social censure and handicap which have notoriously, within our lifetime, shown a strong tendency to diminish.

I do not find Malthus's reasoning cogent or impressive, and hope that I shall not be accused of misrepresenting it in the above brief summary. What will not, I think be disputed is that Malthus's doctrine was advanced by him and used by its later adherents as a doctrine of political or social economy, and only incidentally or occasionally as embodying sound counsel for the ease and security of particular families. The social problem was thought to consist in the disproportion between the numerical increase of a group—a national or political group, for example, or the whole of a group within which regular commerce prevailed, and so possibly, if intercommunication became sufficiently penetrating and prevalent, between the increase of the whole human race—and the resources available for its physical maintenance, not in the mere inconvenience which adventurous or unfortunate parents might fear or encounter in trying to rear a large family. If members of such families grew up and prospered at the expense,

as might sometimes happen, of the less vigorous or less fortunate children of more prudent parents, the liberal political economy of the nineteenth century was not equipped with any argument against the desirability of such competition.

The decline in the reputation of the old doctrine of population, and, less directly, of other economic doctrines connected with it, is often declared, and I think rightly, to be related causally to the actual adoption in many countries, including our own, on a large scale, of the practice of prudential restraint—in the form not mainly, or to any extent relatively important, of the deferring of marriage to a later age, but of the express and deliberate limitation of the number of children born to parents capable of producing them. Statistical data concerning numbers of children born, the age and sex distribution of the population, and other facts which are relevant exist for our own and for many other countries, though no one contends that the statistics are perfectly accurate, no unformed person would, I suppose, contend, either, that they are completely worthless and misleading. The official statistical data naturally throw no light on the means by which the reduction of the number of births is secured within the marital relation, and we are compelled here to have recourse to other sources of information which are in their way ample and obvious to those who care to attend to them, but not, like the figures published by governing authorities, precise and statistical.

A fairly persistent decline in the birth rate is shown in the public statistics of this country during the last fifty years, and, roughly speaking, during the same period the same tendency is shown in the statistics of other countries of Western civilization. The phenomenon appeared considerably earlier in France and in certain sections of the population of the United States of America, and there are other variations also which would prevent us from insisting upon the seventies of the last century as a critical period for the natural increase of the population of these areas. It is noteworthy, also, that a diminution in the death rate has been, generally speaking, a characteristic of the same period, and that the statistics of births and deaths, taken together, have not in most countries given rise to lively apprehensions of a net diminution of population or even of a future failure of the population to increase. Such apprehensions have found expression in respect of the French population, and in the United States in respect of the relatively native or settled population, as opposed to the recent immigrants. American statistics are said to be manifoldly imperfect, but they enable conclusions to be drawn as to the rate of reproduction of various classes of the population, and they show, for example, that relatively more children are born to unassimilated immigrants than to the pure Americans. That the rate of increase may be "differential" as between different classes of the population is a matter to which importance is naturally, though not in all cases very reasonably, attached. We must return presently to this subject, noting for the moment that the population of a particular area may be recruited and increased by immigration, and, of course, diminished by emigration, that such movements have taken place in recent periods on an enormous scale, and that they have occasioned political and economic changes of the first magnitude.

The British statistics yield, indirectly at least, much information to the effect that the decline in the birth rate is "differential" also in our community, and more especially that birth control prevails more widely among the relatively better situated. Other sources of information are accessible here also, and it may be treated as notorious that the restriction of births is not confined to the well-to-do, and that large families, and especially large families of undesired young children, are to be found mainly among the poor. Mortality in early years and shorter life might be expected to be more frequent in this class also, and those who fear for the parentage and upbringing of the future adult population of this country are properly reminded of this connexion between high birth rates and high death rates. An observation which may frequently be made does not, however, lose

its impressiveness through the consideration just mentioned a married couple, for example, admirably equipped according to the prevailing standards for the decent upbringing of children, rears to maturity two children or only one or none. In the first case the couple is, to use the common phrase, just "reproducing itself" if its children reach maturity, and it is not even doing this in the two other cases. If we think of such parents as a class of eminently good citizens—apart from the possible dereliction of duty in this respect—and of conduct like theirs as prevalent in the class which possesses the like eminence, we may be led to feel alarm at the prospect of the failure of the "best" elements of the community to reproduce themselves.

It is not surprising to find that the propagation of children can be urged as a duty towards a social group or members of that group, as I think we may see at once by attending to the following sentences from Sir Arthur Newsholme's work on *The Declining Birth Rate* (1911):

"It cannot be regarded as a matter of indifference whether the unfilled portions of the world shall be peopled by Eastern races (Chinese, Japanese, Hindoos, etc.), by negroes, by Slavonic or other Eastern European peoples, by the Latin races, or by the races of Northern Europe."

Every Briton will wish that his race may have a preponderant share in shaping the future destinies of mankind" (pp. 57 and 58). Whether we have in these sentences moral and social teaching which will bear rigorous philosophical examination or not, no one will question the assertion that these and similar statements would command a general and spontaneous assent among members of the groups to which the appeal implied in them is made. The average Briton is, I suppose ready at once to prefer that persons of his race should enjoy in the present and the future such and such kinds of preponderance, and to do so not merely with an unoffended, but with an approving conscience. His group reactions towards other "races" are notoriously more fluctuating. We can readily imagine also a preference, more or less deliberate and more or less vehement, similarly manifested at the prospect of a particular country being peopled by the adherents of this or that religion and the larger families of Roman Catholics, for example—not unconnected apparently with the attitude of the Roman Catholic Church towards birth control—have already excited apprehensions and hopes in certain communities of the effects on future public policy, the prevalence of mass numerical and disciplined voting obviously gives a certain definiteness to these apprehensions. I have referred already to certain fears which have been expressed concerning the relatively small number of children which are now being reared in middle-class surroundings and traditions. It is not perhaps so well known that opposition has also appeared in some labour or socialist circles to the propagation of birth control among the working classes, on the ground that the future voting and political and industrial "fighting" force of labour would be thus diminished.

It would obviously be rash to argue directly from the general assent, which statements of the kind just quoted would command, to the future conduct in their personal and private relations of the persons assenting, and it is important here to keep in view the possibility of mass effects on the conduct of large groups rather than effects in isolated instances. The average individual is not apt, I suspect to pass immediately from his general preferences for the social and political future to any shoddering of a share—which to him personally is heavy, but may turn out to be insignificant in the mass—of the costs of bringing about such a result. Accordance with his other inclinations and interests, persistent group pressure and example, and like causes may sometimes come to the aid of such ideal and remote aspirations.

That discussion of changes in the number and distribution of the population is often strongly affected by class interest and bias is obvious to all who are acquainted with it, and this view has been strengthened, I hope, by the preceding sections of this paper. Scientific and more especially economic discussion of the subject should, it might be claimed, be unbiased and disinterested, and should address

itself to establishing and exhibiting general relations between the changes of population and the conditions of subsistence and prosperity. The old law of population offered such a statement of general relations in terms of natural phenomena, distinguishing, indeed, between the successful and the unsuccessful competitors for food and existence, but containing no suggestion that the division of population into hostile groups was anything but an incidental result of its excessive number. The unprosperous were broadly and simply the numerical excess of months for which Nature, even when subjected to the utmost pressure from the available labour, did not provide. Economic writers who accepted this law of population did indeed occupy themselves largely with the conflicts of groups, the suppositional errors of Governments, and other such matters, but they did so with this apparently simple and austere law in the background, beside which the group conflicts of actual social life could, at any moment, be made to appear theoretically insignificant results. Modern economists, as I have pointed out, are not even vaguely agreed on any simple doctrine of population which could perform the debating functions of the older one. Many of them would, however, recognize the scientific importance of the notion of the "social class"—that is, of groups of persons similarly situated in respect of their modes and opportunities of livelihood, and distinguished thereby from groups which differ in this respect. Obvious and notable differences, constitutive of social classes, arise out of what we must be content to call generally the distribution of property or of "capital." Much more is involved in this distribution than the mere distribution during limited periods of the actual products of industry. The quantity of the products created and made available, and expected to be created and made available, also depends upon it.

From this point of view it becomes necessary in discussing the actual growth of population in the areas with which we are concerned to take account of the political and social divisions which prevail in them and to seek to discover how they affect the conditions of the problem. We cannot pass directly from propositions concerning the generosity with which Nature produces human beings, and the ingardliness with which she produces the things which they happen to need for their subsistence, to the actual problems of a society which obviously does not enjoy the use of more than a small fraction of the resources available to it for its sustenance and comfort. It is true also that we cannot learn in a few lessons to perform marvels of explanation by using the notion of the class war and of the catastrophe to which it is inevitably leading us.

It must be remembered, too, that our existing social institutions and situations are not ultimate facts, however important it may be to understand them, but are only a stage in the development of processes economic and non-economic. We can properly contrast them with such ideal constructions as we are able to conceive theoretically and to approve morally as reasonable and just. In doing this we may derive confidence from the reflection that our thoughts and aspirations have a claim to be considered as parts of the process which I have just mentioned.

I must now summarize briefly what I think a representative of economic science finds himself in a position to say on this aspect of the problem of population, and I must first show what I conceive to be, and not to be, the proper and peculiar object of economic inquiry. Economics deals specifically with a certain aspect of the conduct of men as members of social groups—that is, with such of their deliberate and not merely impulsive acts as are directed to the non-violent, and in this sense peaceful, but onerous or costly, acquisition of external things, the performance of labour and the exchange of its products being the typical and important modes of such peaceful acquisition. It does not study greed or covetousness, nor does it even indirectly commend them. It deals with an aspect of the conduct of every reasonable and responsible person, however generous his ideals and motives may be, and with any disposition which such person may make of his labour and his means with a view to acquiring results of labour and exchange without waste, that is, without unnecessary or superfluous expenditure or cost. The "economic man" or

the man who is, or is assumed to be, wholly absorbed in the acquisition of "wealth" is not the proper or peculiar object of the science of economics

Both the things which we "demand" or seek to acquire and the terms on which we can acquire them are to a large extent socially determined, departure from the normal expenditure of the social group or class is difficult and, practically speaking, not possible for its average member. The consideration given by economists and others to what is sometimes called "consumption," to fashion and to its changes, yields uniformly this same result. The interested stimulation and direction of demand with a view to profit is a very strongly marked feature of modern civilization, and has consequences of a kind especially important for our present purpose in the sense of creating uniformity of demand and in breaking down class barriers, in so far as these depend on habitual differences of expenditure. "The standard of life proper to a class" is not so constant a notion as to make its more or less assured attainment a source of deep satisfaction or confidence in the future, and this standard is not apt to include under modern conditions the rearing of a large or even of a small family of children.

That the children of a family should in certain circumstances be looked upon as a source of economic strength to it, and accordingly that the upbringing of children should be encouraged by the persuasion that the condition of parents will be easier when the children come to earn, need not shock or surprise us, unfamiliar to our personal experience though such express calculation may be. The possession of some undertaking in which children, as they grow up, can help or to which they, or some of them, can succeed is a condition obviously favourable to the parental habit, though it will obviously again not always impel in the direction of large families, and parents thus situated may exhibit, as a class, habits which might be rashly enough attributed to some parental instinct or impulse. Again the following remarks of Dr Newsholme (p. 40) ought not to evoke merely cynical comment, but should rather inspire confidence in the economic study of social facts. "In the earlier years of these [the textile] industries each child was his parents' savings-bank, from which savings could be drawn as soon as the child could go to the mill as a half-time. Now the age at which the child's immature strength can be exploited has been retarded, and the child is a less profitable asset than in the past." Doubtless, Dr Newsholme views with satisfaction the diminished exploitation of the child's immature strength, and probably none of us would defend it against him. But the interest of this instance, in which some of the causes of birth control are manifested, should not be exhausted in an expression of satisfaction at the disappearance of the half-time system; we may see how the elements in a class or group situation are connected, and how measures which must have some good effects may also tend to destroy the economic unity of the family. Practically, we may feel ourselves urged to promote measures which tend towards family coherence under better conditions than those of the half-time system.

In the above instance, and in general, economic inquiry brings into prominence the connexions observable in the situations of groups and classes, and it substitutes insight into such connexions for such beliefs as the belief that important differences in social conduct are traceable to the persistence of profound or fundamental differences, of a psychological or biological kind, between individuals, and thus between the various groups which the individuals constitute. Thus, for example, in the above instance, we should say that the large families of textile workers in the half-time period were not the result of the peculiar greed and of the hard calculating temper of an inferior breed or "race" of men who happened to be textile workers, but were the result of the intelligible reactions of average human beings to given situations, and that the average person forced from one social situation into another tends to put off the habits fitted to the old and to assume those fitted to the new, even to the extent of changing some of his estimates of virtuous and vicious conduct. Even when, as may happen, the

transition encounters friction; strange habits and points of view become easier to "understand" in the sense of intelligent sympathy, if not always of abstract and intellectual comprehension. Economic inquiry tends, I think, to destroy utterly the impression that, corresponding, roughly at least, to the social divisions, there is a division of the people of this island, for example, into biologically distinct breeds or races, some of which are fitted by origin and nature to bear rule over the others. It is true enough that an economist as such will not be allowed to claim the last word in the matter, but he has or should have some special qualifications to examine such claims as (1) that the economic advantages of the relatively comfortable classes are the result of the prevailing excellence of their merely biological descent, (2) that these classes exhibit aptitudes for leadership and command which are in danger of perishing to the great loss of society if their stock is not continued, and (3) that in order to continue their stock they must be relieved of some of the taxes which now fall upon them, and otherwise favoured at the cost of the governed classes, who are now being pampered by doles and other public concessions and thus encouraged to propagate their inferior stock. That grievances with which we can sympathize underlie such contentions is obvious enough, but they are grievances which, like those of other groups, must be understood in the light of the general social and economic situation. This will probably appear to members of my audience, as it appears to the average economist, not to be one which should satisfy any informed and thoughtful person, and certainly not of a nature to pamper the unprivileged masses. They suffer, like many of their envious critics, from ignorance and from the lack of security and hope.

I will only refer briefly to the general problem of eugenics, with the intimation that I should like to hear the question discussed in a medical conference, if, as is possible, the issues raised and some of the proposals made are felt to be of interest. Some advocates of eugenic proposals advance contentions which economic inquiry is not called upon directly to endorse or to refute, and I may mention as an obvious instance some of the results based on the measurement of skulls. With the social and economic situations to which these results are applied the economist obviously must concern himself, and he has had occasion to regret the lack of economic interest sometimes shown by the students of corporeal measurements and the devotees of craniometry.

On certain other matters the economist would also wish to be better informed, and would gladly recognize that there is no method proper to the science of economics by which he can investigate them. The effect on conduct and habit generally of a widespread dissociation of sexual gratification from parental responsibility is such a matter, and so are certain other consequences of childless marriages and of very small families. Gratification at some of the results of birth restriction is widely expressed, and there is a tragedy in the birth of "unwanted" children which I need not try to impress upon my present audience. But there are many such aspects of the matter which future experience and inquiries not properly economic may be expected to illuminate. That men should know and choose, rather than behave as blind victims of impulse and despair, would seem to be in general a ground for confidence and hope.

To what used to be considered, and what probably is in fact, the main economic question, the question which the "law of population" purported to answer, I would offer the following definite reply. The obstacles to the growth of population, and the causes of misery and restricted livelihood in the mass of the people, are not those suggested in the "law of population" as lying in the ingenuity with which Nature responds to human labour and co-operation and science and goodwill. I do not think that our own island, to say nothing of what has been called our little planet, is overcrowded, or that our difficulties are due to any approximation to such a calamity. Our troubles are due, not to the efforts of free and equal people to win a livelihood, and are accordingly not "economic" in any such simple sense, but to causes which I may distinguish

as political, that is, to habits and institutions whose origin and purpose is mastery and privilege and monopoly. Much of the political activity and enthusiasm and the divisions created by them, to which we are trained to attach supreme importance, is viewed economically, a cause of pinched and anxious livelihood for large masses of the population, and these masses are, or are becoming, sufficiently educated in certain directions to contrast the prospects offered to themselves and their successors, both with the apparent productive capacities of our civilization, and with the sacrifices demanded of themselves. That justice should prevail over the whole economic community and not merely, if that were possible in such isolation, within the boundaries of particular States, is seen to be the main condition on which the continuous unfolding of productive capacity depends.

Economic doctrines concerning the advantages of the division of labour, and the dependence of the effective division of labour on the extent—that is, the numerical frequency—of the market, would be meaningless if it were not possible for a region to be more thinly populated than would be desirable, or for a community to suffer disadvantage, even apart from military and political considerations, from its too small numbers. Or again, a community may suffer from the fact that its population is too thinly spread over the area available to it, and that portions of its population are too closely crowded in particular centres and favoured areas. These possibilities do not admit of brief explanation and illustration, and I mention them here with a view to suggesting that the task of the economist is a more complex and more hopeful one than it was thought to be in the days when the niggardliness of Nature and the imprudence of parents were always at hand, to be invoked at need to account for almost every shape of social misery and calamity.

III—THE MEDICAL ASPECT

BY

SIR THOMAS HORDGER, Bt K CVO, M.D., F.R.C.P.,
Physician in Ordinary to H.R.H. the Prince of Wales,
Physician to St Bartholomew's Hospital

Even since I yielded, reluctantly, to the invitation to open this discussion from the medical side I have searched my mind very thoroughly for reasons which might be set against my original protest—that the subject before us seemed to me to be very largely outside the doctor's province. Whether or no my distinguished colleague has felt the same difficulty I cannot say, but up to the moment of writing these words I have had no opportunity of reading Lady Barrett's remarks, and so one of my last hopes has had to be relinquished.

To the Biologist, yes, and to the Economist again yes—the subject clearly has great interest for both of these students, as is manifest from the able papers presented by my two predecessors. But to the Doctor, the population problem seems to me to overlap very little his usual activities, and this whether his work lies mainly with the individual which sick or with that reputedly higher and larger function termed the prevention of disease. In short, the question of over-population or under-population seems to me to lie largely outside the doctor's sphere.

And yet I have enough confidence in the wisdom of those who choose the subjects of our annual discussions, and nominate the speakers, to believe that there is, after all, a medical aspect to this question of the falling birth rate. I therefore propose to examine the matter as well as I am able.

We are told that the problem of population resolves itself into three elements: natality, mortality, and migration. Surely, it will be said, the doctor has a good deal to do with the first two of these? If the doctor is not concerned with birth and with death, who is? But a closer look reveals the fact that the aspects of real determining value in regard to both of these things, as they are related to population, lie outside the doctor's province.

Take the case of natality. The age of marriage, a fact

having great influence upon natality, is almost wholly governed by economic conditions, and medical men have little or nothing to do with this side of the problem. Fertility, and even sterility, are at present questions which lie beyond the ken of the physiologist, let alone the doctor. If we exclude syphilis, a known cause of sterility, there is little or nothing of pathological importance known to us as operating in this direction, and therefore little or nothing that we can do to remove this deterrent to natality. Sex incompatibility, too, is a complete mystery to us, and even if we knew exactly upon what it depends its prevention would seem to be a matter for the eugenisists rather than for us.

Beyond all these things lie the laws which govern the function of reproduction, laws which so far remain inscrutable. We have to await solutions of these problems by the biologist, whether physiologist or biochemist, before we can prescribe appropriately for the patients who come to us inside this sphere.

Mortality. But we doctors function here, it will be said. And it is true that both in preventive and in curative fields of action there are things we can do to prolong life, our efforts do seem to achieve something in this direction, though here the main credit may really lie more with the sociologist than with the doctor, albeit the former relies upon the latter for stimulus and direction. Be it observed, however, in this connexion, that merely to prolong life is but a feeble contribution to population adjustment, and serves us in poor stead in the main issue: *saving* life, however, and improving health may serve us well, since these things may be done at all ages, and therefore at the child-bearing period in women and during childhood. In Germany it has been shown that whilst there is an increasing duration of life, there is also a rapid fall in the birth rate. In effect, old age is on the increase—a parlous state of affairs, and a grim reward for the doctor's contribution to the population difficulties. Such a condition of things must, of course, eventually show itself by an increasing mortality rate—a consequence which will doubtless be set at the doctor's door.

Let me turn for a moment to the actual position as we understand it. To a visitor from another planet much of our attitude towards the population question during recent years would seem very puzzling indeed. A few years ago many of us were not a little concerned about the dangers of over-population: we are to-day met together to consider the falling birth rate. If our visitor were human like ourselves he would probably agree with the poet that there is only one thing common to us all, and that is discontent. But, as I read the position, the present concern is not with the falling birth rate in absolute terms, but with the fact that it possesses differential values of an undesirable kind. It is generally conceded that a low population in any country is a serious affair, because the quality of a population is wont to suffer by a fall in its quantity. The crux of the situation would therefore seem to be the difficulty of securing a regulation of births as between the different social grades in a country. It would appear that this difficulty depends for its solution upon the differential use of family limitation. If so, we have once more reduced matters to a sociological, or economic, or eugenic platform.

The more I examine the matter the more convinced I become that until, and unless, the doctor associates himself closely and definitely with eugenic and economic principles, his opportunities of influencing the population problem are very small, not to say insignificant. But is this really the doctor's sphere? That he would prove a powerful ally, both to the eugenisist and to the economist, I have no doubt whatever. But does society expect him to function in this wise? Is he briefed for this particular advocacy? Until now he has not concerned himself with questions of family limitation, or only to give advice and instruction when husband and wife have already decided upon their course of action. With few exceptions he has not sought to influence men and women upon matters of principle, and he has kept clear of propaganda. He has a sanction for individual therapeutics, but he has hitherto not considered that he possesses any other sanction on

this matter. Even in the important subject of birth control he has very largely stood aloof, regarding jealously his lien over matters of individual health, and not risking his patients' confidence on the personal issue by voicing his opinion in regard to economic and eugenic questions. Is he right, or is he expedient, in this attitude? Has the time come when he should enter the field on the side of these larger issues? I think the point well merits discussion. If it be decided ultimately that he should do this, then he should be taught a good many things that are not now included in his curriculum, and his thoughts should be directed quite early to this vital question of the regulation of births, which is clearly the ideal to aim at. Such regulation presupposes, as has been said, "the economic encouragement of those parents who rise above the lowest levels, since it is the superior performance of numerous healthy parents which now requires moral and material recognition on the part of society."

It may be interesting to glance for a moment at the sort of advice the doctor would find himself giving, and the kind of effort he would be making, in his practice, if ever his help were really sought and given, in an attempt to carry such a rule as this into effect. Professor Grotjahn has indicated for us the elements of conduct which the operation of such a rule as I have specified would involve. The lifting of parenthood on to a rational basis in eugenic practice would imply the three following duties:

1 That every married couple would be in duty bound to bring up a minimum of three children above the fifth year.

2 That this minimum must be aimed at wherever the situation of the parents gives expectation of descendants not falling below an irreducible minimum standard. In this case, however, the minimum must not be exceeded.

3 That every married couple characterized by particular virility should have the right to double the minimum, and should receive for every child in excess material contributions, which would be exacted from the single and from those couples which for any reason whatsoever remain below the lowest number.

When, by the exercise of some such rule as this, the situation of the population has been safeguarded and the general quality raised, the professor considers that the rational use of contraceptives may follow undisturbed. The reward promised for observing a rule like this is the desideratum which all thinking folk desire—the checking of fertility in those social strata which have least means, room, time, or capacity for the upbringing of their offspring.

I have stated the matter thus explicitly because it is just as well to realize clearly the sort of problem the doctor would find himself "up against" were he to embark upon the task of discouraging pregnancy for eugenic as well as for therapeutic reasons. It is a task before undertaking which we may well be forgiven for pausing. And it must be obvious to us all that we should need, not only public sanction, but Government assistance and a system of penalties before we could even begin to make any progress. A merely pious expression of hope that in some Mosaic-like fashion differential reproductivity of a beneficial kind will arrive as the result of arousing eugenic interests in the doctor's mind does not advance the matter in the slightest. We are all eugenic in our attitude towards racial progress, but I doubt very much if the onus lies with us of initiating a carefully considered scheme by which alone such progress can be attained. I feel strongly that the will to improve the race must first be aroused by the sociologist, and that the study of the population problem, especially in relation to the differential birth rate, must be taken much further before the doctor's aid is sought. In summing up the discussion on this subject at the Geneva conference last year, Professor Julian Huxley remarked that, "from our point of view as scientists, one fact will emerge very clearly, and that is the lamentable insufficiency of the data we have on which to base any conclusions."

I have already referred to the fact that the profession has very largely, up till now, whether deliberately or sloth-

fully, stood aloof from the question of pregnancy control. I do not now refer to the therapeutic aspect of the matter, but to the social aspect. I may be peculiar in this, but I feel that such aloofness has been justified by the obvious lack of data upon which to form a sound judgement. I would go further and say that, as pregnancy control is only a part, and probably a small part, of the population problem, the principles governing its exercise do not, in the first instance, lie with the doctor, for reasons I have already adduced.

But the study of contraception is quite another matter, and the inventing or devising of methods, and judging of their success or failure, are certainly matters that concern the doctor. A number of cases present themselves to every busy practitioner where the therapeutic indication for family limitation is definite, and sometimes even imperative. Another important question which clearly lies within the doctor's province, with which, indeed, he alone can deal, is whether or no, and if so to what extent, the use of contraceptives is a factor in the production of disease local or general. Dr. McCann has expressed himself as quite convinced that pelvic diseases are fairly frequently traceable to this cause. But more investigations are required before we can come to any definite conclusions on the point.

Both in the cases in which there is a definite therapeutic indication for controlling pregnancy, and in the cases in which married couples have settled for themselves that it is their duty to avoid pregnancy and the doctor considers he is under an obligation to help them to carry out this decision—in both these cases our present available methods are lamentably defective. There seems to be no clear teaching on the part of our gynaecological colleagues, and many of them appear to regard the subject as taboo. I think this is a great pity.

The fact which emerges most strikingly from a consideration of the subject is, as I say, the completely inadequate means that are at our disposal in advising a patient.

In summarizing very briefly what these means are, such a conclusion becomes all too obvious. A certain very common method of pregnancy control, besides being quite impossible for many men, is such a gross physical and psychological offence to both parties that to continue to consider it at all is, as I have pointed out, only to pander to that itch which some people possess to be thoroughly inclusive, however impractical, in their survey of possibilities. To tell the partners to restrict the sex act to that period in the woman's menstrual cycle when she is least likely to conceive involves two great objections: first, that this reputed time of low conceptivity is relative only, and therefore cannot be relied upon, and second, that this period varies much with different individuals, and therefore cannot be calculated with safety. There is even a third objection to this method: a woman's time of relatively low procreative power by no means always synchronizes with her time of high sex desire, to adopt this method is therefore tantamount, in many instances, to the sacrifice of that very spontaneity in the union of the sexes which it is sought to preserve. As a writer has aptly expressed it, "practices founded upon this notion may not be in harmony with our present ideas of sexual justice."

Chemical contraceptives fail in that if they are physically harmless they are unreliable, and if they are dependable they are capable of endangering health. Mechanical contrivances have little more, if anything, in their favour. When adapted to the male partner they carry physical and physical disadvantages for which their effectiveness scarcely compensates. If it falls to the woman's lot to make the mechanical adjustment necessary to achieve the object in view we, at present, know of no contrivance the use of which does not involve (for success) manipulation approximating to gynaecological acumen.

It is a question whether the contraceptive method generally advocated at birth control clinics as being the survival of the fittest is not too crudit or too uncertain ever to be popular. A friend of mine, who interests herself much in birth control clinics, and who, being fully persuaded of the need and of the wisdom of these clinics, is unlikely to minimize their value, tells me that their "follow up"

system reveals the startling fact that in only about 50 per cent of the cases do the contraceptive demonstration and practice prove effective.

It seems clear, therefore, that if it be granted that individual cases presented to the doctor in his routine work offer legitimate opportunity for advice concerning the checks to pregnancy, he has at the moment very poor make-shfits to deal with. If, in addition, it be deemed part of the doctor's duty to deal with pregnancy control as a part of the health and happiness of the community as a whole—and the two things have very different bearings—the knowledge at present available to secure the desired results is lamentably deficient. Here at least, seems a subject deserving of inquiry, and concerning which the doctor's opportunities for research and observation are abundant and his conclusions paramount. It is a sound thing that he should proceed to extend his knowledge on these matters with the hope that by the time the public has made up its mind on the question of pregnancy control and in the event of such a principle being established he may have something worth offering as his contribution to the eugenics of the population problem.

IV—INDICATIONS FROM STATISTICS

BY

LADY (LORANCE E) BARRETT, M D, M S

CONSULTING OBSTETRICAL AND GYNAECOLOGICAL SURGEON ROYAL FREE HOSPITAL.

BEFORE attempting to discuss the falling birth rate from a medical point of view it is necessary to define what we mean by the term "birth rate." The methods of stating the birth rate in common use are three:

1. The crude birth rate—or rate per 1,000 of the population living at all ages in the middle of the year.
2. The proportion of registered births to the women living at child bearing years—that is, roughly 15 to 45 years of age.
3. Dividing legitimate from illegitimate to state the number of legitimate births per 1,000 married women aged 15 to 45 and the number of illegitimate births per 1,000 unmarried women aged 15 to 45.

It is the third method only which will give us information as to the changing fertility in married women and as to the relative number of illegitimate births in proportion to the unmarried women.

In his book on vital statistics Sir Arthur Newsholme shows by the adjoining table how misleading the crude birth rate may be in comparing two districts like Kensington and Stepney, since Kensington has a large number of single women engaged in domestic service.

Legitimate Birth Rates in Kensington and Stepney 1921

	Kensington	Stepney	Percentage Excess of Birth Rate in Stepney over that in Kensington
A Birth rate per 1,000 inhabitants —	38.1	24.2	73
B Birth rate per 1,000 women aged 15 to 45 years	55.7	98.8	77
C Birth rate per 1,000 married women aged 15 to 45 years	163.0	207.4	27

Sir Arthur Newsholme has also shown very vividly by the example of Ireland that the crude do not always give the same indication as the standardized birth rates.

In that country the crude birth rate was 215 in 1881 as compared with 33.9 in England and Wales and was 23.1 in 1901 as compared with 28.4. Standardized rates in Ireland and En. and respectively were 35.2 and 34.7 in 1881, 36.1 and 28.4 in 1901. Thus Ireland whose crude birth rate was approximately as low as that of France had a true rate of fertility as high in 1881 as, and much higher in 1901 than England. The reason for this remarkable change in the relative position of the two countries

produced by arithmetical corrections is that while in England in 1901 the number of females aged 15-45 per 1,000 of the total population was 250 and in Ireland 235 the wives at ages 15-45 in England formed 46.8 per cent and in Ireland only 32.5 per cent of the females of the same age. The case of Connaught in 1901 is even more striking. Its crude birth rate was 21.3 as compared with 28.4 in England while its standardized birth rate was 38.1 as compared with 28.4 for England.

We see therefore, that the proportion of married women of child bearing age in any country is a very important factor in considering crude birth rates.

Diminished fertility of marriages as a cause of the falling birth rate can only be judged by a comparison of the standardized legitimate birth rate in any two periods under discussion—for example, when the birth rate was high (in 1870), and to day.

What has been the decline and when did it begin? We find that the birth rate in England and Wales was at its highest point in the decennium 1871-80. Since then up to 1910—that is during the pre-war era—the birth rate reckoned by either method had steadily declined.

Mean Annual Birth Rates (England and Wales)

	per 1,000 Living at all Ages	per 1,000 Women aged 15-45 years	Legitimate Birth Rate per 1,000 Married Women aged 1-45	Illegitimate Birth Rate per 1,000 Single and Widowed Women aged 15-45
1851-60 —	31.1	164.9	231.0	18.3
1861-70 —	35.2	151.0	287.3	18.1
1871-80 —	35.4	153.6	237.5	15.1
1881-90 —	32.4	138.7	274.6	12.6
1891-1900 —	29.9	122.7	250.3	9.6
1901-10 —	27.2	109.0	221.6	8.2
1911-15 —	23.6	91.4	169.7	7.8

The reduction up to 1910 was

In the crude birth rate	33 per cent
Standardized married birth rate	25
Standardized illegitimate birth rate	46

Birth Rates and Fertility 1871-1925 (England and Wales)

Period	Legitimate Births—		Illegitimate Births—		All Births—
	Per 1,000 Total Population	Per 1,000 Married Women 15-45	Per 1,000 Total Population	Per 1,000 Unmarried Women 15-45	Per 1,000 Total Population
1871 (1870-72)	33.3	292.5	1.96	17.0	35.3
1881 (1880-82)	32.3	285.0	1.65	14.1	34.0
1891 (1890-92)	9.4	263.8	1.31	19.5	30.7
1901 (1900-02)	27.5	235.5	1.12	8.5	28.6
1911 (1910-12)	23.4	197.4	1.03	7.9	24.4
1921	21.4	176.3	1.02	7.9	22.4
1922 —	19.5	160.7	0.89	7.0	20.4
1923 —	18.9	155.3	0.82	6.5	19.7
1924 —	18.1	148.4	0.78	6.2	18.8
1925 —	17.5	143.5	0.74	5.9	18.3

The difference between the crude and standardized figures is what we should expect from the effects of the war. Fewer women could marry and therefore fewer children would be born, but there remains a reduction in the absolute fertility of marriages, and a decrease of illegitimate children. This reduction in the fertility of marriage has been assumed to be due to birth control.

One of the problems for the medical profession is to determine the relative importance of voluntary use of contraceptive measures and of other factors as causes of the diminished fertility of the race. For other causes of variation it is interesting to study conditions which existed before contraceptive measures were known or practised appreciably in any class. In doing so we find

1. That there have always been variations in fertility in different classes.

Children Born per 100 Families—Standardized Rates

Date of Marriage	Duration of Marriage in Years	Upper and Middle Classes	Textile Workers	Miners	Unskilled Labourers
1805-11	0-5	70	76	105	100
1901-05	5-10	171	185	263	242
1856-61	10-15	242	275	359	352
1871-76	15-20	303	359	517	453
1885-91	20-25	357	435	610	541
188-86	25-30	413	501	671	596
1871-81	30-40	497	557	717	652
1851-71	40-50	606	648	777	715
181-61	50-60	662	695	797	763
	over 60	682	732	870	781
Total		277	319	433	392

Consider one example from this table—the families who had married in 1871-81 and who had lived thirty to forty years in wedlock. The actual figures of the numbers of children born in those thirty to forty years to each 100 families are upper and middle classes 497, textile workers 567, miners 717, unskilled labourers 652—that is, the average family varied between roughly five in upper and middle classes to just over seven in miners. It must be allowed, however, that some marriages were probably sterile.

This variation in fertility has been further increased in the last fifteen years. Therefore some factor or factors in the lives of different strata of society affect fertility apart from artificial or voluntary interference, all the factors, including contraception, tend to diminish the upper, middle, and textile classes only.

2 Another factor affecting the natural fertility of marriage is the age of the parents. The age of the father is secondary in importance, but has some influence. Roughly it may be stated that fertility in the healthy man remains stationary between the ages of 20 and 35 and tends to decrease after. The age of the mother in its effect on fertility is more important and has greater variation. Actual fertility increases from the age of 15 to 25, when the age of maximum fertility is reached, and after remaining more or less stationary for a few years declines from the age of 30 to that of 50 in a steady curve.

Actual fertility is much greater before than after the climax. The fecundity of the mass of wives is greatest at the commencement of the child-bearing period and gradually declines, after the age of 40 the decline is very rapid.

The following tables illustrate various details in connexion with the fecundity of marriage viewed from the point of view of the wife.

1 The first shows the effect of the age of the wife at marriage on sterility.

Proportion of Sterile according to Experience in Scotland of 1855

Ages at Marriage.	Proportion Sterile
15-19	15.6 per 100 wives
20-24	1.5 " "
25-29	22.5 " "
30-34	32.3 " "
35-39	50.0 " "
40-44	87.0 " "

2 The second shows (a) the initial fecundity according to age at marriage—that is, the percentage of women who bore children in the first year of marriage, (b) women who bore children within the second year of marriage, and (c) the percentage of women fertile at any time.

Ages at Marriage	Percentage Fertile in First Year	Percentage Fertile in Second Year	Percentage Fertile at Any Time.
15-19	13.71	43.71	92.7
20-24	18.48	90.51	100
25-29	12.41	75.8	72.3
30-34	11.44	62.93	62.5
35-39	9.27	40.97	46.8
40-44	3.63	15.45	9.1
45-49	0	4.35	4.4

Therefore nearly all women married between the ages of 20 and 25 are fecund—that being the age of climax of fecundity. The fecundity of the very young (15-20) is greater than that of those married between 25 and 30, but the total fertility is less. These figures illustrate exactly in how many instances the use of contraceptives in the first year of marriage is unnecessary for the prevention of immediate child-bearing.

Fertile women after sixteen years generally had an average family of 4½. Persistently fertile women—that is, wives bearing children up to the end of the child-bearing period—have an average family of 11½.

From these considerations we see that marriage under the age of 20 does not appear to be the most successful for child bearing, and this is supported by the development of children born of very young mothers.

The average weight and length of children at birth vary with the age of the mother. This is shown in the following table.

Age of Mother	Average Weight	Average Length
15-19	6 lb 15 oz	19 0 in
20-24	7 " 3 "	19 1 "
25-29	7 " 6 "	19 3 "
30-34	7 " 4 "	19 2 "
35-39	7 " 4 "	18 9 "
40-44	7 " 2 "	18 9 "
45-49	6 " 14 "	18 16 "

Hecker approves the above figures of Duncan, but thinks increase goes on till the end of fertility, age not being the only factor. The number of pregnancies also has an influence. The highest average in weight and length is found in the children of women aged 25 to 29. Matthews Duncan thinks the weight and length increase with successive pregnancies, but does not doubt the accuracy of the age influence.

Considering the total fertility of wives married at varying ages, we find that the very young marriages are the most prolific, thus girls married at 15 to 19 years of age will after thirty years of married life have an average of 9.1 children, while those married between the ages of 25 and 29 will after thirty years have an average of 6.3 children. Early marriage, therefore, *per se* in any community will increase the birth rate, but the development of the children born in the early years will tend to be lower than where the marriage age is 25 to 29. These considerations all point to 25 as the best age for marriage.

Another point of interest to our inquiry is the proportion of male births, because it brings with it some knowledge

Wholesale prices are shown by the broken line sex ratios at birth by the continuous line

of another factor bearing on births. The accompanying chart gives Stevenson's figures regarding the relation of prices to masculinity.

Male births are always more numerous than female, but the proportion varies from time to time in this country and also varies in different countries. From 1870 to 1915 the highest point to which masculinity rose was 1,043 in

1875 the lowest being 1 033 in 1888 and 1890. In 1918 it reached the height of 1 060. The variations in different countries need not be described here, they will be more readily explained when the cause of changes in our own country is more clear.

We are now in a position to see that certain conditions obtain to-day which, apart from any artificial means, would tend to reduce the birth rate.

1. The later age of marriage. This we have seen, affects the birth rate in various ways. (a) It diminishes the total fertility of the family. (b) It lengthens the period between marriage and the birth of the first child. (c) It tends to lengthen the space between each child.

2. Conditions affecting the fertility of husbands. All gynaecologists meet with cases of sterility in which no abnormality can be found in the woman, but if before subjecting the woman to any treatment necessitating an anaesthetic the semen is examined in a number of cases it is found to be inactive. One of the causes of this is gonorrhoea. This also accounts for sterility in some women, but a man may have followed careful advice and abstained from marriage till non-infective, and though the wife remains healthy yet conception may be impossible. The work of Professor Leonard Hill on the sterilizing effect of heat (even body temperature) on the male cells suggests the possibility that sedentary indoor employment may account for some diminution in fertility of men of certain classes.

3. Of the factors which affect the relative fertility of different classes we have, however, no certain knowledge, but since the same differences existed in 1855 we know that it is not only due to the better knowledge of contraceptive measures, even though it were shown that there is in certain classes is very widespread. If relative prices and hence relative luxury and relative want affect the masculinity, it may also have an effect on total births.

4. Before drawing conclusions we must bear in mind that there are certain natural laws which, if obeyed, would affect the birth rate, and we must make allowance for the probability that in certain classes they have been a factor. (a) It is well known that ill health in either sex is marked by lack of desire for sex indulgence. If the mother is debilitated by too closely following pregnancies or the father is worn out by stress of mental work, she or he does not desire sex gratification. (b) In more developed races where sex is associated with love, desire for the wishes and well-being of the object of affection forbids intercourse when it is not desired, but we know that in many instances intercourse takes place in spite of failing desire. (c) It is significant, however, that where either partner consents to intercourse against his or her desire the result is unsatisfactory to both.

Nature thus provides a kind of natural eugenic law which, if obeyed, protects the mother from the burden of pregnancy when health is becoming impaired and protects the race by allowing conception to occur only when both parents are in full health. Nature's law would only allow large families where the parents are both virile, healthy, and free from mental anxiety or stress. Such results would obey the laws of eugenics, but we must admit might strew the resources of the parents in the matter of upbringing and of education. With the economic aspect, however, I am not dealing at the moment.

From the medical point of view much would be gained by obedience to these laws. (a) It would abolish motherhood in the overstrained woman, whether the overstrain resulted from too frequent child bearing, from overwork, or from unhealthy conditions of environment, because women under these circumstances usually lose sex desire. On the other hand, if intercourse takes place in ill health, with or without their consent, the result is more prolific child bearing than in the normally healthy woman. (b) Pregnancy under conditions of health produces an enhanced sense of vitality and well-being and is not a time of illness or invalidism, the expectant mother's efficiency is not impaired. (c) The dangers of child bearing are diminished in women who enjoy mental and physical health.

This obedience, however, may be said to be an ideal, unattainable in the case of exactly those instances where frequent child bearing is taxing the strength and resources

of the mother to the uttermost. This is undoubtedly true at the moment, and yet if we regard this subject with an unbiased mind from the point of view of prophylactic medicine we find that the ideal coincides with the health of the race. It is therefore the duty of the medical profession—itsself possessed of the highest ideals—to pursue and teach them to those able to receive them, just as it is our duty in the practice of our profession generally to aim at prophylaxis and only secondarily at cure. But we do and must aim secondarily at cure when prophylaxis fails and in this question of the birth rate under the present unsatisfactory conditions of large numbers of people Nature's law does not obtain, and the health of many poor women is being destroyed by overwork and over-child-bearing. In such cases it is, in my opinion, our duty to see that child bearing is modified and that the conditions of life are changed.

The influence of the doctor on both factors is essential, otherwise no progress will be made, and the doctor will be reduced far years to the unsatisfactory empirical treatment of some form of conception control. With regard to the first—the modification of child bearing—in the absence of the co-operation of the husband we are at present left with the problem of finding some method of preventing conception.

I do not propose to discuss here the various forms of contraceptives in use except to express my own opinion as to the undesirability of the various rubber instruments recommended. They are unreliable—that is, although they may prevent conception in a large number of women they entirely fail in many others, witness the fact that scarcely any advocates of them remain who do not combine with them the use of a spermicide. They are in many cases harmful. The clinics where they are in use have no records of systematic examination by the cervix with speculum to ascertain whether cervicitis occurs, and it is the only way of knowing if the cervix is damaged or if abnormal discharge is present. The observation recorded by the patient herself is valueless. I have found cervicitis a frequent result.

If conception is to be prevented the more harmless methods, in my opinion, are the use of the sheath and the introduction of medicated pessaries made up to the prescription of a doctor. But, regarding this subject from a purely medical point of view, we must also remember that sex indulgence to any excess produces nerve exhaustion, and contraceptive methods in the cases we are discussing are not a cure for the mother's debility.

The responsibility of the doctor for advice as to contraceptive measures is only one part of his duty, whether the doctor is the medical attendant of the family or the hospital physician or surgeon. Sources of ill health and disease are often found in the conditions of life of the sufferer, and the influence of the medical attendant in calling attention to the lack of ordinary hygiene in the lives of working-class mothers is as important as the duty of those medical inspectors who insist on hygienic conditions in factories.

Is it not time that doctors spoke clearly as to the lack of change and rest and of outdoor exercise among other factors in the lives of the mothers who bear large families? There are, however, some cases in which the recurrence of pregnancy is a matter of life and death to the woman—for example, severe heart or kidney disease, or even recurring puerperal insanity. If in such cases the co-operation of the husband is not obtainable sterilization should be performed, as it is the only absolutely certain method, apart from complete abstention from intercourse.

We conclude that medical practitioners have an important part to play in this question of the falling birth rate. In some cases duty demands that they teach the advantages of normal marital relationship, in others it may be their duty to do all in their power to help a potent to avoid pregnancy. They cannot stand aside and take no part in directing teaching, advising, and treating their patients. They cannot disregard eugenic considerations, their views and advice on conditions of life which cause debility and abnormal fertility are valuable, and, if frankly expressed, would be of real service to public health.

I make the most earnest claim that the family doctor should be the person to deal with this subject, whether with or without consultation with special clinics or consultants. I submit a few reasons for this in summing up some of the points to which I have drawn attention.

1 If the true facts, as shown in the above tables, about the chances of immediate conception and natural rate of child-bearing were explained, many young couples would begin married life naturally, unhampered by artificial contrivances. Such explanation is best given by the family doctor.

2 Most people of education in marriages of true affection would respond to the doctor's advice that it is not for the good of themselves or of their offspring to come together when either does not desire it.

3 The doctor knows the whole circumstances of the case in question, and how pressing or otherwise is the demand for some means of preventing conception, which may vary from avoiding a risk which would be almost certainly fatal, to anxiety as to whether financial resources will adequately maintain and educate another child.

It has been said that the medical practitioner is unable or unwilling to deal with this question, and has no training to equip him for giving wise advice suitable to each case.

I suggest that the remedy for this is that all that is at present known in regard to this subject should be taught to medical students, and then responsibility in regard to it be emphasized. If the family attendant refuses help in this respect it cannot be a matter of complaint if patients seek knowledge and helpful advice from a practitioner who is willing to give it.

One last word as to the medical aspect of the present situation from a wider point of view. The birth rate of the artisan class is falling most rapidly, but closely comparable is the fall in the upper and middle classes. The birth rate is actually rising among miners and unskilled labourers—that is to say, classes in economic comfort are becoming unnaturally sterile, while classes in or approaching destitution are unnaturally prolific.

In physical values, if only through being reared in unfavourable environment, the latter must be lower in vitality than the former, and as the proportion of healthy members of the race is gradually diminished and the proportion of ill-developed members is increased, the physical standard of the national health must deteriorate.

From a medical point of view the position is disastrous, and would not, in my opinion, be cured if all contraceptive practices were swept away. We should thereby add somewhat (though not to the extent imagined) to the stock of those who can afford physical necessities of health, but more drastic measures from a public health point of view are needed to arrest the fertility associated with destitution.

A CASE OF OSTEITIS FIBROSA.

BY

J LEIGH COX, M A, B M, B Ch Oxon,
MRCS LRCP
BRISTOL SOUTH DEVON

THE following case presents some points of interest, and may be considered worthy of publication.

A girl, aged 18, cashier in a draper's shop, complained of "cutting pains" in the right knee, which gave out when she was walking. The pains were intermittent, did not incapacitate her from work, and lasted from October to December, 1926.

On Christmas Eve, 1926, she complained of pain in the right tibia, and took to her bed on January 4th, 1927. She then noticed a swelling about the middle of the tibia, and the pain became definitely worse. On examination I found a uniform swelling apparently involving the whole circumference of the bone at the junction of the upper two-thirds and lower third of the right tibia. There was some tenderness on deep pressure, but no other physical signs any-

where. No history of any blow or injury could be elicited. An antero-posterior x-ray photograph was taken of the right tibia and fibula, and showed a small area of rarefaction at the site of the swelling. A provisional diagnosis of chronic osteomyelitis was made, and the patient kept in bed, her temperature and pulse being carefully watched. At the end of a fortnight the pain had subsided and there had been no rise of temperature or pulse. The patient was allowed up and told to report again should there be any recurrence.

In March, 1927, she complained of a gradual onset of pain in the right hip-joint, saying that she got very stiff on sitting down and could not walk on rising. On examination there was a quarter of an inch true shortening of the right leg, marked limitation of movement on abduction, and some tenderness on pressure over the joint. A skiagram showed marked rarefaction of the neck of the right femur, with a spontaneous fracture extending about half way across it. The upper half of the shaft also appeared to show rarefactive changes. The patient was put to bed for three months and given tab parathyroid and calcium (P D and Co) thrice daily, and began to walk again in August, 1927. There were no more symptoms, and another skiagram was taken in October. This showed rather more marked rarefaction in the neck of the right femur, but the fracture appeared to be healed.

In April, 1928, the patient again complained of some increase in size of the tibial swelling, with slight intermittent pain in this situation. A lateral view of the tibia revealed an extensive area of rarefaction with marked thinning of the bone. Permission could not be obtained for removal of some blood for the Wassermann reaction and calcium content estimation.

The comparative rarity of this condition and lack of definite knowledge concerning the fundamental metabolic errors responsible seem to make this case worthy of record. The condition is sometimes associated with parathyroid tumours, in this case there were none discovered.

Radiogram of right tibia and fibula April 4th 1928.

A CASE OF PARTIAL STAPHYLOMA OF THE CORNEA

BY

R Y STONES, M C, M D, M R C P Lond,
MEEROO HOSPITAL, KAMPALA, UGANDA

A STAPHYLOMA corneae parziale, the scar of which is giving way, complicated by a staphyloma totale of the other eye, is a somewhat rare condition, so the following case seems to be of sufficient general interest to merit publication.

A young South African farmer, 18 years of age, living at Eldoret, some three hundred miles from Kampala, had a severe infection of both eyes when 3 years old. His parents were on trek miles away from any town, and it was only by the good offices of a regimental surgeon whom they fortunately met that the child's sight was not entirely lost. As it was, the one eye was completely and the other partially blind. The boy first went to school when he was 16, but at his first half-term holiday it was noticed that his sight had deteriorated a little, so on the advice of a doctor he was removed from school and took up farming. The father reported that the sight had again begun to fail during the last two months.

When seen on August 31st, 1927, the left eye was found to be completely blind, the cornea being replaced by a dense leucoma, the tension of the eye was very low. The right eye showed an elastic cornea except at the lower and inner quadrant, where an old leucoma was present. This scar had given way in the centre and the iris was protruding. No corneal ulceration was found, and there was no oedema of the conjunctiva. The anterior chamber was shallow and the tension of the eye subnormal; the iris was excentric, showing the presence of anterior synechiae, vision was only 3/60. The fundus could not be seen, a red reflex only being obtained, with a +20 lens strab could be seen in the lens vitreous opacities were not found.

It was decided that an operation must be performed, and this was conducted according to the method described by Alradie.

Operation—(1) The corneal tissue over and around the staphyloma was scarified with a sharp scalpel. (2) A "bridge" flap of conjunctiva was got ready and preparatory stitches were inserted. (3) The base of the staphyloma was incised with a Graefe cataract knife. (4) The flap, which covered the staphyloma entirely, was stitched in position. The lens did not escape. The patient did not take the anaesthetic well, and the operation had to be done quickly.

Ten days after this operation the scar again began to give way and the tension was still low, the conjunctival flap having apparently slipped back. Cocaine was instilled and the flap brought over again, after denuding the surface of the cornea. The patient was kept at absolute rest with a firm pad and bandage over the eye for three weeks. Graduated exercises were then begun, but the scar again began to bulge, the anterior chamber was almost gone, and the tension, which had improved after the operation, again fell. A further more radical operation was therefore necessary if the eye was to be saved; this was carried out under rectal anaesthesia.

Second Operation—(1) The conjunctiva was dissected

back all round the hialus and a purse-string suture inserted. (2) The cornea was scarified around the staphyloma. (3) The staphyloma was excised and two fine catgut sutures were used to draw the edges of the wound in the cornea together. (4) The base of the staphyloma was cut through with a Graefe knife. (5) The purse string suture was tied, drawing the conjunctiva well over the cornea.

A very severe reaction followed this operation, and the eye took ten days to quieten down, the scar which resulted was firm, but in spite of atropine being pressed the iris was drawn over and vision was perception of light only.

Owing to the severe reaction and the unstable condition of his eye the patient was advised to go home for some weeks before an optical iridectomy was done.

He was readmitted on January 2nd, 1928. It was then seen that a firm white scar had formed, the iris was bright and the eye quiet, the anterior chamber was deep and the tension nearly normal. A simple optical iridectomy was done. Two days later a severe reaction set in with an effusion of blood into the anterior chamber. The eye again slowly quietened down, but the vision was only hand movements. No red reflex could be obtained. The lymph and blood clot in the anterior chamber slowly cleared up and the vision improved daily. The patient could soon count fingers at three feet and could distinguish distant objects fairly well.

As the reaction after a simple operation had been so sharp it was considered inadvisable to do anything further for the time being, as the boy could find his way about independently and both he and his parents were satisfied. A month later the mother wrote saying, "The eye is improving. He can see quite well now. He is very happy and is out riding almost the whole day."

I wish to record my thanks to Dr H B Owen DSO, medical superintendent Mulago, who saw the patient in consultation and who shared with me the anxiety of the case.

Memoranda:

MEDICAL, SURGICAL, OBSTETRICAL.

TETANY INVOLVING THE RECTUS ABDOMINIS

The following case, which came to my notice recently, seems to be worthy of record, both on account of its rarity and of its somewhat abrupt termination.

A married man aged 53, of rather poor physique complained of symptoms of ordinary influenza—namely cough, coryza, malaise and headache of two days' duration. These symptoms did not inconvenience him so much as that during this time he had experienced agonizing pains in the upper abdomen which came on at any time during the day and night. He described them as just like a stitch or cramp. So severe were they that sleep was impossible. Nothing seemed to relieve them and they disappeared after five to ten minutes only to return. He had noticed that the attacks were induced more readily by stooping. His temperature was 99.4° F, pulse 100. The mucous membrane inside the nose was intensely congested and the nares patulous; the result of chronic nasal catarrh. Nothing beyond a few catarrhal signs was present in the chest.

While I was examining his abdomen he was seized suddenly with one of these cramp-like attacks and I was able to witness the course of events. In the epigastrium there gradually appeared two somewhat sausage-shaped swellings extending transversely on either side of the mid-abdominal line. They were slightly thicker towards the mid-line, tense of board-like consistency and there could be no doubt that they were the upper segments of the rectus abdominis in spasm. He was in great pain during the attack. At the same time the skin over the abdomen was hyperaesthetic and he could not bear me to touch him. I witnessed several attacks that night each lasting from five to ten minutes. The upper segments alone were affected and went into spasm synchronously on one occasion however, the left half only was concerned. Further examination revealed hyper-excitability of the face and tapping over the pes anserinus elicited fibrillary twitchings of the facial muscles on that side not quite amounting to spasm. I could find no other physical signs in the nervous system and no fibrillation in any voluntary muscles though his spare musculature seemed at first to suggest progressive muscular atrophy. I ordered 10 grains of compound ipecacuanha powder with 10 grains of aspirin in powders and a saline expectorant mixture. Two days later I saw the patient again; the cramp had then disappeared entirely and his influenza was much better.

There could be no doubt as to the nature of these tonic spasms. Their gradual and orderly onset excluded

the possibility of localized myoclonus, for here the contractions are almost always shock-like in their intensity and onset, and usually involve the peripheral muscles of the limbs. Moreover, there is frequently a history of mental deterioration or epilepsy, in this case both of these were absent. I am inclined to believe that I was witnessing a case of tetany involving the rectus abdominis, and the presence of Chvostek's signs tend to confirm this.

Though cases of toxic tetany are rare, Frankl-Hochwart mentions its occurrence in acute specific fevers, of which influenza is one. As compared with the number of cases associated with infantile rickets and post-operative thyroidectomy these toxic cases form a very small percentage.

For the rectus muscle to be involved alone seems altogether unique. I can find no mention of a similar case in the literature.

TRIPLE INTUSSUSCEPTION IN AN ELDERLY WOMAN

The unusual occurrence of a triple chronic intussusception occurring in an elderly woman seems to be worthy of record, particularly in view of the diagnostic difficulty and the recovery following operation.

A married woman aged 57 was admitted to my wards in the Glasgow Royal Infirmary suffering from absolute constipation, constant vomiting and acute pain in the abdomen. She stated that she had not been well for a year or so with gradually increasing constipation, the passage of slime by the rectum and pain particularly on the left side. The pain became very severe and the constipation almost absolute vomiting began and she went to another hospital where she was x-rayed and the abdomen was examined but nothing abnormal was found. A week later she returned and was examined under an anaesthetic but again nothing was found and she was sent home the following day she came to the Royal Infirmary.

On admission the abdomen was found greatly distended so that palpation was impossible. Peristaltic waves were frequently seen in spite of the distension. The tongue was very dirty and the breath foul; the temperature was 98° F, the pulse 88 and the respirations 26. Rectal examination was negative and an enema yielded no result. Carcinoma of the large intestine was considered the probable diagnosis.

The abdomen was opened, and since the large bowel was distended it was incised but without much relief. An exploration was therefore made, and a hard mass was felt which at first was thought to be a large impacted gall stone. When this was brought to view it was found to be a triple intussusception of the small intestine. The two outer intussuscepta were very easily reduced but there then remained a third small hard one, evidently of considerable standing, and obviously irreducible. A short-circuit was therefore performed, and the patient made an uninterrupted recovery.

J A C MACFARLANE, M B, C M, F R F P S,
Surgeon Glasgow Royal Infirmary

HERNIA OF INTESTINE THROUGH A MESENTERIC HOLE

The following case seems worthy of record for its interest in regard to diagnosis and its peculiarity.

A boy, aged 8½, complained of sharp stabbing pains in the lower abdomen and of sickness. The pulse was 110 and the temperature 99.8°. The face was deeply flushed with circumoral pallor, the tongue was very coated and almost of the 'white strawberry' type. On inspection of the abdomen nothing abnormal was noted, although the mother stated that she had seen a definite swelling on the right side. There was pain on palpation over the appendix region.

Under anaesthesia a swelling as large as an adult's fist was noted in the right iliac region. On opening the abdomen the caecum was found to be very much distended, the lower part of the ileum caecum appendix and lower part of the ascending colon had slipped, from behind forward through a hole of about two inches in the mesentery becoming twice twisted on itself. The hole in the mesentery had smooth thickened edges and round it were some enlarged glands. The part of the intestine involved was untwisted and pushed back through the hole in the mesentery, the hole closed and the boy has made an uninterrupted recovery.

Four years previously this boy had complained of abdominal pain, and his father had been told by a colleague that the condition was probably tuberculous. I am indebted to Mr Edmund, who operated, for permission to publish this case.

JOHN WHITE, M B, Ch B Ed

FOREIGN BODY IN THE BLADDER

The following must be a rare accident, but should be borne in mind by those who are doomed to a "catheter life" owing to enlargement of the prostate.

An elderly man of more than average intelligence was admitted to the Colony Hospital, Grenada, on December 4th 1926 with a history of having passed a rubber catheter on himself the tip broke off when he tried to remove it. He had been carrying out this form of treatment for several months and had had no previous trouble.

On admission the patient was in great pain and collapsed, he was suffering from marked retention of urine with a bloody discharge from the urethra. A metal sound was gently passed into the urethra and was found to be held up by a resistant structure at the neck of the bladder. The prostate was found on examination to be considerably enlarged and very tender on palpation per rectum.

I performed a suprapubic cystotomy and a piece of rubber catheter about two inches long jammed tightly in the urethral orifice of the bladder was removed. The prostate which was markedly enlarged and congested and bulging forward appeared to surround it. There was a fair quantity of blood in the bladder, which was drained. On December 9th a tiny fragment of rubber was passed per urethram. Three days later there was a sudden and large haemorrhage from the prostate which was only controlled with great difficulty. Intermittent haemorrhages followed for six days after which there was no more trouble. Drainage was continued for some time afterwards, and on January 1st 1927 the patient was discharged from hospital passing urine freely per urethram. He refused to have prostatectomy performed.

My interpretation of this accident is that, after passage of the rubber catheter, the man had spasm of the neck of the bladder and urethra, and in his hurry and fright he wrenched at the catheter against the contracting urethra. It is notorious that rubber deteriorates rapidly in the tropics, and no doubt the catheter in question was not in good condition.

Since writing the foregoing I have been interested to read Mr A. Ralph Thompson's account of two similar cases on January 14th (p. 51), where fragments of catheter formed the nuclei of vesical calculi.

V L FERGUSON,
Chief Medical Officer and Resident
Surgeon.

St. Lucia, British West Indies.

VON RECKLINGHAUSEN'S DISEASE ASSOCIATED WITH FIBROMA OF THE APPENDIX

The following case illustrates an unusual condition of the appendix and emphasizes the fact that in von Recklinghausen's disease the distribution of the tumours is wide and variable, and by no means confined to the skin and subcutaneous tissue. It has previously been shown that intra-abdominal neuro-fibromata can simulate the commoner abdominal affections.¹

A man aged 47, is afflicted with neuro-fibromatosis having large numbers of nodular tumours, some sessile and some pedunculated, over the scalp, neck, face, trunk, and limbs. The tumours vary greatly in size. The accompanying photograph gives a good impression of the appearance of the patient. In addition, there are numerous subcutaneous tumours and areas of pigmentation on the back and lower limbs. A slight degree of hesitancy in the speech is noticeable, a condition said to be characteristic of this disease.²

He consulted me on March 31st last on account of abdominal pain and said that five days previously he began to suffer from intermittent abdominal pain which was colicky in nature and not localized in any particular area. The pain had continued but in the last forty-eight hours it had become localized in the right side of the lower abdomen where he had since felt a tender swelling. There had been no vomiting and the bowels had acted regularly except for an attack of diarrhoea on the second day. His temperature was 97° F, pulse rate 72 and respirations 20.

In the right iliac fossa an elongated mass was felt which was distinctly tender on palpation. The abdomen moved fairly well with respiration.

On the same day he was admitted to hospital where an operation was performed by Dr H. S. Jeffries. The abdomen was opened through a right paramedial incision. The mass was found to be the appendix which was much enlarged and closely adherent to the caecum from which it was dissected. There were no other adhesions and no other abnormality was found in the abdomen. On examination of the appendix after removal it was seen to be about 2½ inches long and in places about 1½ inches in diameter. It was of fairly hard consistency, and in one place a subperitoneal nodule was seen. The pathological report was to the effect that the appendix was surrounded by fibrous tissue in the form of innocent tumours of the type met with in neuro-fibromatosis, there was no sign of recent infection of the appendix itself.

Before the operation the possibility of the case being fibroma of the appendix was considered, though infection of the appendix could not be excluded.

Petersfield House

TREVOR HOEY, M B, B Ch

ACCIDENTAL SNARING OF TWO SMALL STONES BY A CATHETER

On May 15th a male child, aged 1 year, was admitted at noon for stone in the urethra. When the patient was brought on to the operating table it was found that the stone had passed back into the bladder. A No. 3 rubber catheter was tied in and the operation deferred to the next day, owing to the temperature in the theatre being too high for any but the most urgent surgery to be attempted. The catheter worked well during the night, and on the operation table one ounce of lotion was run into the bladder through the catheter. The bladder was then opened suprapubically. An assistant was asked to remove the catheter so that the interior of the bladder could be properly palpated. He found some difficulty in doing this, and presently the nose of the catheter appeared at the meatus alongside the other end of the instrument. When the loop so formed was pulled out it was found that two small stones—the larger one weighing 35 centigrams and measuring 5.5 centimetres in length and 3.5 centimetres in breadth—were caught in the loop and had been pulled by it through the urethra. No undue force was used in pulling out the catheter. There were no more stones in the bladder.

Reviews.

SELF-HELP FOR DIABETICS

Dr J J CONYBEARE first published his *Self Care for the Diabetic* in 1926, it was noticed in our columns on January 1st, 1927 (p 18), and it has proved such a useful handbook for diabetic patients that a second edition¹ has now appeared. The general plan of the book is to explain to the patient the principles which govern his treatment. Diabetes is a disease in which the victim, if his life is to be lengthened and rendered more useful, must understand thoroughly the relative parts played by insulin and diet. He must realize that, notwithstanding the wonderful effects which the injection of insulin can produce, his health and strength depend in a much greater measure upon a properly balanced diet which is rigorously adhered to. Wisdom and understanding are essential to the preservation of the diabetic. Hence a simple book like Dr Conybeare's can be placed in a patient's hands without fear of making him morbidly introspective or unduly apprehensive. The greater part of the book consists of admirable hints on dieting, with a chapter on cookery for diabetics, giving specimen menus for properly calculated meals. In this second edition Dr Conybeare has emphasized the great dangers which may attend the use of so-called diabetic foods. A short chapter is devoted to describing such urine tests as a patient ought to be able to carry out. Full directions are given for the self-administration of insulin, and a sound epitome of hygienic rules for diabetics helps to complete a most sensible book.

Planned somewhat on the model of Dr Conybeare's handbook is Dr HENRY JOHN'S *Diabetic Manual for Patients*. It may be that the average diabetic in the United States brings to the study of his disease a greater interest in, and deeper knowledge of, human physiology. Dr John, at any rate, devotes considerable space to anatomical and physiological details, which strike us as being somewhat beyond the grasp of the average patient in this country. However, since the author makes apt use of similes taken from the motor car and its engine, it may be that he has made his descriptions intelligible to any patient who is a motorist. But when he comes to the practical advice as to the administration of insulin and the arrangement of the diet Dr John puts his points in the simplest fashion, and his pictorial illustrations are first-rate. An appendix by Miss Laura Soden, dietitian in the Cleveland diabetic clinic, furnishes one of the best series of diabetic menus that we have seen. Dr John's optimism as to the possibility of diabetic patients establishing sufficient carbohydrate tolerance to enable them to discontinue the use of insulin is most encouraging. It will be worth while following his directions with meticulous care if such degrees of improvement as he quotes can be obtained at all generally.

FROM MAGIC TO SCIENCE

It was a happy thought on Dr SMOEN's part to bring within one cover under the heading *From Magic to Science* various essays which have issued from his pen during the past ten years. The historical student, especially, will be glad to have these articles with the author's latest emendations in this easily accessible form. They range in subject-matter from such general headings as "Science under the Roman Empire" and "The Dark Ages and the Dawn of Science" to such specialized and detailed studies as "The Lore of Gildas" and "The Visions of Hildegard". Notwithstanding this diversity of appeal, the book is certain to be welcomed by even the general reader, since, apart from the intrinsic interest of the essays themselves, they are profusely illustrated with excellent reproductions taken

from illuminated manuscripts and early printed books. In short, Dr Singer has prepared a volume which delights the eye while it stimulates the mind.

Whatever be the subject of the essay, whether the wide panorama covering hundreds of years or the microscopic examination of a single life, or a particular book, Dr Singer walks with an assured step, and speaks as one widely and intimately acquainted with the facts. Serious students of medical history will, however, have a real grievance against him, since he gives hardly any references. It is doubtless an easy matter to make a parade of scholarship by filling the bottom of each page with references to authorities transferred from other writers who, in many cases, have copied them from someone else. In Dr Singer's case we may be sure that if he has not actually perused the original he at all events quotes from a reliable authority. Still, a reference would be something to go upon, and the student would have an opportunity of being introduced to some new and, perhaps, very interesting material. Thus, to take one example out of many, it is averred that "Fracastoro followed Lucretius in denying any essential difference between the living and the non-living." This is certainly at variance with what is generally known regarding Fracastoro, and we should have welcomed some indication as to the work in which he made this assertion. Moreover, this lack of reference even afflicts Dr Singer himself. He has paid special attention to Hildegard of Bingen, and must be regarded as an authority on the subject. The date of her death is usually given as September 17th, 1179, but in the first issue of this essay in 1917 Dr Singer definitely placed it in 1180, and even two years ago, he somewhat vehemently denied that her decease took place in 1179. In the present issue, however, "September the 17th, 1179," appears without comment. A note to the effect that he has now found reason to change his opinion would dispel the uneasy feeling that 1179 is here a misprint for 1180. Moreover, it would seem that some of the generalizations proceed upon too narrow a basis of fact, as, for instance, where he says in regard to Cassiodorus that "but for his activity it is possible that no complete Latin literary work, save that of Virgil, would have reached our time." In process of argument, too, there is at times some hastiness. Thus, while admitting that the most beautiful of the early English medical manuscripts and of all the illuminated specimens were prepared in monasteries, it is contended "that there are certain works, such as the Leech-Book of Bald and the Laennec, where the scribe himself must have been a layman." This is emphasized by the frequent demand that certain ceremonies need the aid of a priest, a superfluous direction in a book intended only for monastic use." Dr Singer evidently overlooks the fact that monks were not necessarily priests, and at the date to which this refers the vast majority were not in holy orders. Besides, many of these manuscripts were written in convents by women. On this somewhat insecure foundation, however, Dr Singer, a few pages further on, makes the bold statement, "The Leech Books, whether written in monasteries or no, are, as we have seen, essentially lay products."

As was inevitable from the title, much of this volume is given over to the question of magic. Dr Singer is of the school which holds that magic is a stage in the development of scientific medicine. Whether this is so or not may be open to question, but even as an assumption it is not without its uses. Objection may, however, be quite well taken to the very wide connotation which he has given to the word magic. Thus he would include not merely what is generally understood by the term, but also prayers, litanies, and even the sacramental system. In the section dealing with early English magic and medicine he enters a field which has up to the present remained almost untilled, but his zeal has succeeded in analysing the still existing manuscript fragments and assigning individual portions to no less than eight different sources. The general impression made on the reader is that the early Englishman dwelt in a world of spells and charms. It is difficult to believe this, and the mere existence of these manuscripts gives no indication as to the frequency with which spells, etc., were used. Probably in no case were they employed until ordinary methods failed. We may be sure that the twelve dog-Latin words which are instanced as a charm to arrest

¹ *Self-Care for the Diabetic*. By J J Conybeare, M.C. M.D. Oxon. F.R.C.P. Lond. Second edition. Oxford Medical Publications. London: H. K. Lewis, 1937. (Cr. 8vo pp. xiii + 70. 3s. 6d. net.)

² *Diabetic Manual for Patients*. By Henry J. John, M.D. F.R.C.P. Maj. M.R.C. London: H. Kimpton, 1938. (Post 8vo pp. 202. 4s. figures. 7s. 6d. net.)

³ *From Magic to Science: Essays on the Scientific Twilight*. By Charles Singer. London: Ernest Benn Ltd. 1928. (Roy. 8vo pp. vi + 253. 14 coloured plates. 108 figures. 25s.)

the burning of a house would not have been used by the peasant of that day if a sufficiency of water were available. When that failed this prayer to St Columba would, at least, be as effectual as regards quenching the flames as would cursing at large. In this connexion an incident recorded by Pepys is not without significance. He had heard that carrying the foot of a hare was a preventive against colic. Acting upon that information he proceeded to get his hare. The effect was remarkable, and some few months later his records with astonishment his continued immunity. He, however, like the sensible man that he was, had been taking every morning throughout this period a turpentine pill.

Even those who least agree with Dr Singer's philosophy will readily acknowledge his masterly array of facts. If, in their view, he has given too wide a scope for magic they will be tempted to enlarge their own definition so as to include him as a belated adept in the Art, albeit of the white variety. Certainly, in this book he shows a notable power of evocation, and has found a charm that can unlock the magic casements opening on the musty past.

ORGANIZATION OF HEALTH SERVICES

We are still awaiting the book which will, within moderate compass, present to the public in attractive form some account of the history of the movement for the organization of public health services, the present machinery by which the community attends to its own health and that of the individuals who compose it, the problems to which the complications of this machinery, mainly owing to its haphazard growth, give rise, with an adequate and not unduly biased discussion of suggestions and methods which are being tried or have been proposed for the solution of these problems. Some months ago (*Journal*, October 15th, 1927, p. 688) we reviewed a book by Dr F. F. Fremantle, M.P., entitled *The Health of the Nation*. We now have one entitled *Health Services and the Public*,¹ by Dr STELLA CHURCHILL, a member of the London County Council. The former, as we indicated, should be, with a few adjustments, an admirable "textbook or handy reference book for students of civics, for members of Parliament, of town and county councils, of committees and associations interested in health and social welfare, and also perhaps for senior medical students and qualified practitioners." Its method is to give the bare facts and statistics, usually to avoid expressions of opinion, but never really to discuss the problems that present themselves. Such method leads to conciseness but lessens interest. Dr Stella Churchill's book is intended, we imagine, to appeal to the same classes of persons as Dr Fremantle's. Though not a long book, it cannot properly be called concise, but its chief defect is that it is not interesting. Here again facts and statistics will be found in some abundance, covering an even wider field than that of the earlier book, but in no very logical sequence. Historical details of very minor importance are mingled with others of much greater significance. The expression of opinion is not avoided, but it consists largely in quotations from reports, articles, or speeches of all sorts of persons, some of whom undoubtedly speak with authority on the matters dealt with, but others of whom cannot make quite so strong a claim. All this, of course, discloses the author's great interest in, and acquaintance with, the very numerous branches of the wide subject with which she is dealing, but it seems to argue, also, a certain lack of judgement which may well arouse caution in the reader. A few small inaccuracies have been noticed. One of them is perhaps worth mentioning. The statement is made that "a considerable number of panel doctors, working without partners or assistants, have 2,000 insured persons on their lists, some have 3,000, and even 4,000 is reached," and to this there is a mere footnote "now reduced to 2,000 (1928) without an assistant." The statement in the note is inaccurate, the facts being that the maximum number allowed was reduced to 2,500 (with power of insurance committees to propose further reduction), and that some

years ago. The whole statement is calculated to produce a wrong impression, since it is nowhere mentioned that the average list of an insurance practitioner is well under 1,000, and the number of practitioners with over 2,000 and working single handed does not loom large, while it by no means follows (as is stated) that each of these has a total clientele of some 5,000 persons, and so rushes through his work in order to see his "enormous number of patients." It is evident, indeed, that there is a very strong political or sociological bias running through the whole work. The preference for State action rather than individual responsibility, for the multiplication of municipal clinics for all sorts of special conditions to be used by all sorts of persons, for the whole-time health officer rather than the private practitioner, is, probably of intention, pronounced. It is less easy to see why the attitude of the private practitioner towards preventive medicine is misconceived, or why the great preventive work which he is, as a rule, doing day by day is ignored or denied, or why doubts should be thrown upon the conscientious work, efficiency, and success of the insurance practitioner. Nevertheless, while we await the advent of the ideal book on the subject of public health organization, the reader who learns how to use Dr Stella Churchill's volume will find in it much valuable material and many provocative suggestions.

HAEMOGLOBIN

The second edition of Professor JOSEPH BARCROFT's book *The Respiratory Function of the Blood*, which originally came out in 1914, is now appearing by instalments. The first of these, entitled *Lessons from High Altitudes*, was reviewed in these columns (1926, 1, 56). The second part, *Haemoglobin*,² continues the interestingly written summary of much original investigation, in large measure helped by the Medical Research Council. Less than twenty years ago it was generally held that haemoglobin was the same in all animals, now, with the advance of knowledge, this belief has been very seriously shaken, and its once accepted origin from chlorophyll is now more than doubtful, porphyrin being substituted as the starting-point. Attention is directed to the relations of haemoglobin, haemochromogen, and exochromen, the last term being applied to a range of substances with approximately the same spectrum, and specially investigated by Dr Keilin. In the chapter on the specificity of haemoglobin it is suggested that the differences in its behaviour can be explained, not on the ground that it is built upon a different basis of porphyrin, but because its porphyrin is attached to a different globin. Among the other aspects of the subject treated are its specific oxygen capacity, the nature of what is usually called a haemoglobin solution, the dissociation curve, theories of its union with oxygen, and the effect of temperature on haemoglobin. The last chapter of this volume, though written with a light touch, is highly technical, and will therefore appeal to the man in the physiological laboratory more than to the medical man in general practice, it deals with the biological significance of haemoglobin.

TREATMENT OF GONORRHOEA

An author who can write on gonococcal urethritis in the male and find something new to say is to be congratulated. If he can at the same time write so as to interest his readers and compel even a reviewer, satiated with works on venereal disease, to read his book from cover to cover, he may almost be regarded as a worker of miracles. Dr P. S. PELOUZE of the University of Pennsylvania has done this. In the preface to *Gonococcal Urethritis in the Male*³ he states that his book is not a textbook upon gonorrhoea. "It is just a simple story, simply told, unhampered by the textbook writer's constant fear of leaving out something that his reviewer would expect to find, the reviewer has been forgotten, and the story told as my experience has taught it to me." Would that more writers worked

¹ *Health Services and the Public*. By Stella Churchill. M.R.C.S. Eng. L.R.C.P. Lond. D.P.H. Camb. London. N. Doullas, 1928. (Cr. 8s. 1p. 1x + 256. 7s. 6d. net.)

² *The Respiratory Function of the Blood. Part II. Haemoglobin*. By Joseph Barcroft. London: Cambridge University Press, 1928. (Roy. 8s. 6d. 1x + 200. 6s. 3d. figures. 12s. 6d. net.)
³ *Gonococcal Urethritis in the Male*. By P. S. Pelouze, M.D. Philadelphia and London: W. B. Saunders Company, 1928. (Med. 8s. 6d. 357. 7s. 8d. figures. 24s. net.)

in such a way! Most textbooks upon gonorrhoea leave one with a feeling of confusion and a sense of helplessness. Facts are furnished—too many of them, indeed—but so arranged that it is impossible to draw a lesson from them or to understand how gonorrhoea should be treated. Dr Pelouze boldly steps out of the beaten paths and fuds his way into untrodden country. He has shown a refreshing disregard for some of the idols that venerableologists have worshipped without question for many years. The keynote of his book is simplicity—simplicity in exposition and simplicity in treatment. He views with horror the methods of the instrumentalist, with his array of operating urethroscopes, canter points, dilators, and electrical contrivances. He is equally adamant against the disinfectant enthusiasts who would kill the gonococcus by means of strong disinfectants and aniline dyes that penetrate the epithelial lining of the urethra. He maintains that irrigation of the urethra and bladder achieves its purpose by provoking tissue reaction rather than through any direct action on the gonococcus. The use of too strong solutions or irritating lotions is harmful. The ideal irrigating fluid is that which produces only a mild reaction and a very slight increase of discharge a few hours after use. Success can only be obtained by extreme gentleness on the part of the attendant physician. Over-rigorous methods inflict harm and reap a harvest of complications. Dr Pelouze's book should be read by every practitioner who intends to treat gonorrhoea.

NOTES ON BOOKS

DR. J. ARTHUR MYERS has written a book entitled *Modern Aspects of the Diagnosis, Classification, and Treatment of Tuberculosis*,¹ which is designed to equip the general practitioner and recently qualified student with all the knowledge and experience necessary for a complete understanding of the tuberculosis problem. It is essentially a popular book and must of necessity appeal only to those who have no time to tunk for themselves or to make a serious study of the disease. Indeed, it is difficult to resist the conclusion that the author himself has never studied the disease seriously. In his chapter, for example on the tubercle bacillus we find a succession of wrong and misleading statements. Dr Myers's knowledge seems to be derived mainly from three or four textbooks, some of which are written by authors whose views are very largely discredited. He refers repeatedly to Mantoux's intradermal tuberculin test as the Mantoux test, he says that tubercle bacilli are destroyed by 5 per cent phenol in half a minute, and he has the tiresome habit of saying that such and such a thing has been 'shown' or 'proved,' when the truth is that someone has on some occasion brought forward a highly debatable piece of evidence in favour of it.

On its first appearance RIBBERT's textbook of general pathology and pathological anatomy was recognized as a work of outstanding merit, and enjoyed great popularity for many years. It is now sixteen years since the last edition appeared, and in that interval great advances have been made in the subject and the standpoint from which it is viewed has undergone a complete change. The preparation of a new edition, therefore, involved practically a recasting of the work if it was to be brought abreast of the present time, and it became a question whether it was worth while to undertake the revision considering the number of good books on the subject which are already on the market. Ribbert's book was an outcome of Birch Hirschfeld's textbook, and that, together with the publishers loath to see it drop out of their list. They have accordingly prevailed on Professor STERNBERG to undertake the preparation of a new edition,² and instead of inserting the new material in the original text, which would have produced a patchwork effect, he has deemed it best practically to rewrite the greater part of the book taking care at the same time to preserve the general plan and character of the original. Almost all of Ribbert's figures remain, and sixty additional figures have been inserted. Professor Sternberg and the publishers have done a good work by reinstating Ribbert's book in current medical literature.

Professor and Mrs PLIMMER have just published a third edition of their small book previously called *Food and Health* and now named *Food, Health, Vitamins*.³ This work has evidently satisfied a popular demand, for three editions have appeared within three years. The volume has been revised thoroughly, and gives an excellent summary of present day knowledge of dietetics. Dietetics is undoubtedly a highly contentious subject, and the authors hold strong views of their own, but they give a fair and impartial account of their subject.

Professor C. R. MARSHALL and Mr H. D. GRIFFITH, both of the University of Aberdeen, have joined forces in the production of *An Introduction to the Theory and Use of the Microscope*,⁴ which should prove very useful to those for whom it is designed—students who require a microscope in their studies and amateurs who wish to understand the fundamental principles of microscopy. This textbook is clearly and simply written and amply illustrated, a supplementary chapter gives a mathematical statement of some of the problems discussed in the text.

The Chemistry of Crude Drugs,⁵ by J. E. DRIVER and G. E. TREASE, is described by the authors as an elementary textbook for students of pharmacognosy. It provides, within the space of 160 pages, a short account of the chemical characters of the chief constituents of crude drugs.

¹ *Food, Health, Vitamins*. By R. H. A. Plimmer D.Sc. London and Violet G. Plimmer. Being a new edition of *Food and Health*. London: Longmans, Green and Co. Ltd. 1928. (Cr. 8vo pp. viii + 120. Illustrated. Paper cover 2s. cloth 3s.)

² *An Introduction to the Theory and Use of the Microscope*. By C. R. Marshall M.D. J.L.D. and H. D. Griffith B.A. London: G. Routledge and Sons Ltd. 1928. (Demy 8vo pp. viii + 90. 28 figures. 3s. 6d. net.)

³ *The Chemistry of Crude Drugs*. By John Edmund Driver M.Sc. Ph.D. A.I.C., and George Edward Trease Ph.C. London: Longmans, Green and Co. Ltd. 1928. (Demy 8vo pp. vii + 159. 10s. 6d. net.)

PREPARATIONS AND APPLIANCES

GRIPPING FORCEPS

Mrs DENIS BROWNE, J.R.C.S. (Resident Medical Superintendent, Hospital for Sick Children, Great Ormond Street) writes: 'Some years ago, when devising an instrument for holding that very friable organ the tonsil during dissection, I designed a grip which I believe to be both new and of a fairly wide application in surgery. Its principle is to produce a ruck in the material grasped by its blunt overlapping jaws (A), much in the way of the army regulation fastener for webbing straps. It is obvious that a grip of this sort will tear out less easily in flimsy material than one that depends for its hold on piercing or crushing. The original tonsil forceps (B) proved so popular that I have had two other models made

a tissue forceps (C), which is very useful for holding tuberculous glands, cyst walls and other washy tissues, and a bowel forceps (D) which I think will grip the intestine more firmly and with less damage than anything else I have ever tried. The forceps are manufactured by Messrs Allen and Hanbury, Ltd., Wigmore Street, W.

² *Lehrbuch der Allgemeinen Pathologie und der Pathologischen Anatomie*. Begründet von Professor H. Ribbert. Neu bearbeitet von Dr. Carl Sternberg. Leipzig: F. C. W. Vogel. 1928. (7 x 94 pp. xv + 727. 739 figures. M 45.)

Nova et Vetera.

THE BROMPTON MEDICAL BOOK SOCIETY

AMONG the local medical societies of London one of the oldest must surely be that which has existed for ninety-four years under the name of the Brompton Medical Book Society. It was founded on August 16th, 1834, by a meeting held at the house of Mr Newbery, at which were present, besides the host, Messrs Eisdell, Muller, Godrich, Chinnock, and Dr Boyton. In addition to these, Messrs Green, Coward, Mullus, and Wilson were also original members of the society, though they were unable to attend the inaugural meeting. The founders decided that the society should consist of thirteen members (thus displaying a degree of moral courage which was probably rare in those days), who should pay a subscription of one guinea annually, with an entrance fee of half a guinea. (In later years the membership was enlarged to eighteen.) Elaborate rules were drawn up for monthly meetings, for the purchase and circulation of medical books, for fines, for the election of new members, and so forth. The first three books purchased by the society were *Diseases of the Urinary Organs*, by Sir Benjamin Brodie, *Diseases of the Joints*, by the same author, and Dickinson's translation of *Diseases of the Skin* by Rayer. The first secretary was Mr Newbery.

It has to be borne in mind that in 1834 Brompton was still a village round about where South Kensington Station and Sussex Place now stand, connected with London by a long street of straggling houses known as Brompton Row—now rebuilt as the Brompton Road. So far as the present writer knows, the only house left of the old village is Park Cottage (behind Pellham Street), which is apparently of Jacobean date. In 1820 Fankner estimated the population of the whole district at 3,000, Brompton Chapel (in Montpelier Street) was the only place of worship until 1829, when Brompton Parish Church was built on land previously utilized as a cemetery for those patients dying in St George's Hospital whose relatives could not be found or who would not defray the expense of their interment. Footpads had within quite recent memory infested the neighbourhood of Knightsbridge, where a bridge (as the name implies) carried the main West Road across an open stream, the Westbourne, issuing from Hyde Park, in fact, decent citizens even then stirred out after dark at the risk of their purses or even of their lives. The Half Way House—half-way from London to Kensington, that is—still existed, more or less on the site where the park-keeper's lodge now stands, opposite the top of Ennismore Gardens. This inn was notorious as the resort of the highwaymen who robbed incautious travellers on dark nights at Knightsbridge. It was pulled down about 1845, and a true story about it serves to make one realize how very near, in reality, those apparently far-off times are to the present. Some three or four years ago the Kensington Public Library acquired at a sale a water-colour drawing of the hostelry, and a paragraph appeared in the press to this effect. Within a few days a distinguished looking old gentleman wandered into the library and asked if he might see the water-colour. When the librarian showed it to him he said, "Yes, that's the Half Way House all right, I remember it well." On the librarian remarking that it had been pulled down eighty years before, the visitor replied, "Yes, I know that, I lived opposite to it when I was a boy—indeed, I live in the same house still." He was (the late) Lord Listowel, wounded at the battle of the Alma!

The neighbourhood of Brompton consisted chiefly of large houses standing in extensive grounds, and of market gardens for the supply of fruit and vegetables to London. Even as lately as 1850 there were wheat fields in the Queen's Gate region, at least one retired member of the Brompton Medical Book Society remembers walking through them on his way to school. Chelsea was a similar

village, on the banks of the river, and between the two was Little Chelsea, a hamlet placed on the road to Fulham, where Drayton Gardens now intersects that thoroughfare, and still identifiable by the narrow piece of road which tends to clog up traffic in the Fulham Road at that point. That the society drew members from a wider area than the village of Brompton is proved by the election of Mr Baines of the King's Road in 1834, and of Mr Marshall of Cheyne Row in 1838, it may be further illustrated by the membership list for 1846-47, which also shows how rapid the development of the district was about those years.

Francis Godrich, Esq., Little Chelsea
Alfred Warden, Esq., Robert Street
Franklin Hudson, Esq., Alexander Square
Charles F Pollard, Esq., Brompton Crescent
J D Hewett, Esq., Michael's Place (now Egerton Mansions and Terrace)
E W Pollard, Esq., 1, Brompton Square
J Mould Esq., Brompton Row
Fredk Muller, Esq., Hans Place
Edward Seaton Esq., Sloane Street
Wm Vesalius Pittigrew, Esq., 30, Chester Street.
J D Rodgers, Esq., 2 Upper Ebury Street Publico
Alfred Barnes Esq., King's Road
D O Edwards Esq., Sydney Place
Fredk Genet, Esq., Queen's Buildings Ovington Terrace
Wm Gilbert, Esq., 17, Brompton Square

The most interesting of these names, probably, to residents still alive, is that of Mr John Mould, who remained a member of the society until his death in 1899, and is still well remembered by a good many people of scarcely more than middle age. He was a man of remarkably fine appearance and great personality, who carried on a large practice almost down to his death. The receipt for his subscription of one guinea to the British Medical Association for the year 1858 is still, by some curious chance, to be found loose in one of the early minute-books of the society. The name of the member from Chester Street would have delighted Sir Walter, indeed, it is not impossible that it actually may have delighted him.

It will be noticed that by 1846 very few of the original members retained their connexion with the society. Apparently in 1837 there were dissensions within the fold, and Mr Newbery, who had acted as secretary ever since the foundation, resigned after a resolution, which amounted to a vote of censure on him, had been passed at the March meeting in that year, one or two more of the founders resigned shortly afterwards.

The society took no official notice of the accession to the throne of Queen Victoria, which seems strange when it is remembered that she had been living for some years quite near them all. But they signalized the year by holding the first annual dinner in September, when loyal toasts were doubtless honoured with due enthusiasm. But for the interruption caused by the war, this dinner has been held annually down to 1927. In 1838 a custom was initiated, which has been continued ever since in the society, of presenting a retiring secretary with any medical work which he might elect to receive.

The members were assiduous readers of medical text books, and even ordered such strange productions as Colquhoun on *Animal Magnetism*, *Isis Revelata*, *Kosmos* by Humboldt, and Thompson's *Food of Cattle*. In 1847 it was decided to deposit a number of books—presumably no longer wanted by the members—in the library of the Western Medical and Surgical Society. This was done, and two printed lists, dated 1850 and 1851, are pasted into one of the minute-books showing the books thus deposited. It is regrettable to see that Suow's *Inhalation of the Vapour of Ether*—purchased 1847—is one of these discarded volumes.

In more recent years the society abandoned the purchase of medical books, but continued for some time longer the circulation of medical periodicals. Finally this, too, was given up, and for several years the society has existed for purely social purposes. The doyen of the membership at the present time is Mr J P Bartlett, who was elected in April, 1877, two gentlemen who were members when Mr Bartlett was elected are alive—Dr Hamilton Bland, who is still in practice, and Dr W B Whitmore, who has retired, while yet another contemporary member, Dr Walter Riden, died early this year. Mr G H Pedler

was also of those who elected Mr Barlett, he served as secretary for the remarkable period of thirty three years, and died about four years ago. The society has never had any president or chairman throughout its existence, the chair at each meeting is taken by the host in whose house the meeting is being held and the chairmanship at the annual dinner goes by rotation.

H R

THE SOUTH AFRICAN UNION MEDICAL COUNCIL

[FROM OUR CORRESPONDENT IN CAPTOWN]

With the advent of the Medical, Dental, and Pharmacy Bill on the statute book radical changes will take place in the control of the medical profession in the Union of South Africa. On December 31st this year the four provincial medical councils will cease to exist, and their functions will become unified in the Union Medical Council. This body, by special arrangement, will extend its jurisdiction over the Mandated Territory of South-West Africa.

Constitution of Council

The personnel of the Council will comprise

Two *ex officio* members—namely the Chief Health Officer or an assistant health officer for the Union, and the Commissioner of Mental Hygiene or the physician superintendent of a State mental hospital.

Two medical practitioners, one dentist and two lay members nominated by the Minister of Public Health.

One medical practitioner (who must be a member of the governing body or teaching staff) nominated by each university with a complete medical faculty.

One medical practitioner nominated by the Minister to represent the Mandated Territory.

Ten medical and three dental members elected respectively by the medical and dental practitioners of the Union.

Two persons (who may be either medical practitioners, nurses, midwives or masseurs) elected by the nurses, midwives and masseurs of the Union.

The two members elected by the nurses, midwives, and masseurs will not be entitled to vote on matters which, in the opinion of the president of the Council, do not affect the interests of the classes they represent. It will be observed, then, that, inclusive of the two *ex officio* members, the new Council will contain twenty-five members. At the time of writing the following appointments to its membership have been gazetted:

Government Medical Nominees—Dr A. J. Stals, M.L.A. (Worcester) and Dr H. E. Fernandez (Durban).

Government Dental Nominee—Dr J. A. Stegmann (Bloemfontein).

Ex Officio Members—Dr J. A. Mitchell (Chief Health Officer) and Dr J. T. Dunston (Commissioner of Mental Hygiene).

Lay Members—Mr E. W. Douglass, K.C. (late Attorney General Cape), and Mr W. H. Rood, M.L.A. (Barberton).

Mr E. Barnard Fuller, F.R.C.S. Ed. has been appointed as representative of the University of Capetown.

Elective members of the new Council are to be elected by the medical practitioners of the whole Union voting as one constituency, so that every practitioner, wherever he resides in the Union, can vote for ten representatives, wherever they reside, even though his selection may not include one resident in his own province. It is laid down, however, that not more than four elected medical practitioners, and not more than one elected dentist, shall be ordinarily resident in any one province, and also that each province shall be represented on the Council by at least one medical practitioner ordinarily resident therein. The election will be by ballot, the first taking place by authority of the Minister, thereafter under the authority of the president of the Council.

Procedure

The elected Council will appoint a president, a vice-president, and a treasurer, who will hold office for the term of each Council. Ordinary meetings of the Council will be held half yearly, but special meetings may be convened by the president. The first meeting will be held at Pretoria, but subsequent meetings may be arranged to take place at any other centre to be determined by the

Council. As it is laid down in the Act that the office of the Council must be situated in Pretoria, it is hardly likely that meetings will be held in other centres, unless for some special reason. The Council may appoint committees to which obviously very extensive powers will have to be delegated, owing to the six-monthly intervals between ordinary meetings of Council and the immense size of the area under its jurisdiction. The quorum of the Council will be seven, of which not fewer than four must be medical members. A registrar, who will also act as secretary, will be appointed by the Council and the Pharmacy Board jointly. These bodies may also appoint a legal adviser.

The Union Medical Register

On the coming into force of the Act a Union Medical Register will supersede the present provincial registers, and all persons thereon will have the right to practise throughout the Union. All persons who are or who have been on any provincial register will be transferred to the Union Register without payment of any fee, but all other medical practitioners are liable to pay a fee of £25 on having their names placed on the new Register. Eight registers will be established—for medical practitioners, dentists, chemists and druggists, nurses, midwives, masseurs, medical students, and dental students. The three last-named are new departures. The Council, in addition, may establish registers of dental mechanicians, sanitary inspectors, and various other classes performing functions ancillary to medicine.

Of great importance to medical practitioners are the provisions, introduced in Section 80 of the Act, bringing the question of fees into the purview of the Council. It is laid down in Subsection 1 that no registered person shall make or attempt to make or recover "excessive or extortionate" charges, in Subsection 2 that, unless the circumstances render it impossible, he shall (a) if requested by the patient, or (b) when the fee exceeds that usually charged, state beforehand the fee he intends to charge. In Subsection 3 that detailed accounts must be rendered whenever requested, and in Subsection 4 that any person who contravenes or fails to comply with any of the above provisions shall be guilty of improper or disgraceful conduct, of which it shall be the duty of the Council to take cognizance and to deal with under its disciplinary powers.

Nomination of Direct Representatives

The announcement that nominations for the ten elected members of Council were required to be in the hands of the returning officer not later than July 31st caused much activity in the medical profession throughout the Union. The action of the Federal Council of the Medical Association of South Africa (British Medical Association) in deciding to run a "ticket" in the forthcoming elections has aroused a division of opinion in the profession as to the wisdom of such a course. Whether or not the formation of such a "ticket" can be justified, there is no doubt that no better method could have been devised for stirring up interest and wakening medical practitioners in general to a sense of their responsibilities, for, in the past, elections in medical circles have been distinguished by extreme apathy on the part of the electors. The question of the formation of a "ticket" was referred by the Federal Council to the various branches, and the action of the Cape Western Branch in deciding to organize a preliminary ballot in the area of the Cape Province has proved to be the best solution of how to select representative nominees to compose the "ticket." This Branch circularized every member of the Association throughout the Province, calling for nominations of four representatives for the Province to form part of the official "ticket." A preliminary ballot was conducted, as the result of which four names were submitted to Federal Council. Other branches likewise called for nominations from their members and when the nominations received exceeded the number of vacancies for the respective provinces, a ballot vote was taken.

In this way the names of candidates selected by provinces were placed before Federal Council, who thereupon drew up a list, or "ticket," of fifteen names of candidates from

whom it is recommended members of the Association should choose in voting for the ten vacancies on the Union Medical Council. The official list of the Federal Council has been declared as follows: W. Darley-Hartley, M. R. Diennan, S. J. O'L. Grimsell, and D. J. Wood, representing the Cape Province; W. T. F. Davies, J. Drummond, and G. E. Oddie-Taylor, representing Natal; C. H. Bidwell, S. M. de Kock, and E. R. Smyman, representing the Orange Free State; Sir Spencer Lister, R. P. Mackenzie, A. J. Ornstein, A. W. Sanders, and A. H. Watt, representing the Transvaal.

It must be understood clearly that these fifteen candidates are the official nominees of the Medical Association of South Africa (British Medical Association) representing the organized body of the medical profession in the Union. It is open to any registered medical practitioner, however, to nominate any number of candidates not exceeding the number to be elected—namely, ten—and it is emphasized also that members of the Association are not morally bound to vote for candidates included in the official list. This list is put forward merely to serve as a guide to the electorates in selecting suitable representatives on the Council.

THE BRITISH ASSOCIATION

ANNUAL MEETING IN GLASGOW

(Continued from page 495)

SEVERAL topics of direct and indirect medical interest were considered during the annual meeting of the British Association for the Advancement of Science. We referred last week to the presidential speech of Sir William Bagg, in which he indicated the connexion between science and craftsmanship, it would hardly be overstating the case to remark that some excellent examples of this connexion have been seen in the programme of the proceedings of this past week, illustrating the gain to medical craftsmanship afforded by purely scientific investigations.

In the Section of Physiology Dr. H. E. C. Wilson reviewed the nature of the material stored during nitrogen retention, using first Voit's conception that the food protein was built up into a labile circulating protein, which was metabolized by the cells relatively easily as compared with the more stable tissue protein. Pflüger, however, held that all ingested protein became an integral part of the living cell before it was metabolized. Investigations planned on the superimposition method had shown that when equilibrium was attained the body excreted the same material qualitatively as was ingested. When, however, the nitrogen output was rising, the material retained was found to be relatively poor in sulphur, correspondingly, when the nitrogen output fell, the material lost was relatively sulphur-poor. This evidence that material "in transit" was poor in sulphur was in accordance with the belief that the sulphur moiety of the protein molecule was more quickly metabolized than the nitrogen moiety. Professor Noel Paton reported recent work on the relation of guanidines to tetany, and a discussion on cell structures was built up by Professors Bronte Gatenby and Charles Walker, and Messrs. Rogers Brambell, D. Sc., and L. A. Harvey, M. Sc. Lactation and the nutritional factors associated with it was the subject of another discussion. The remaining topics in this Section included pulse velocity, a new type of recording oscillogram, simultaneous colour contrast, resistance and polarization in the human skin, the metabolism of iodine, fatty acid as a source of carbohydrates in diabetes, and the measurement of ultra-violet radiation.

The Relation of Physiology to Other Sciences

In his presidential address to the Section of Physiology Professor Lovatt Evans referred to the close association which from the earliest times had existed between physiology and medicine to the numerous contributions of physiology to medical science, and to its influence on the development of medicine, surgery, pharmacology, and hygiene.

He recalled more especially Harvey's fundamental physiological work and revival of the experimental method, which now formed the permanent basis of medical as of physiological knowledge. In this country the teaching of physiology fell for a time far behind when compared with that on the Continent, where Ludwig in Germany, who obtained a separate chair of physiology in 1865, and Claude Bernard in France, had raised the subject to a high level by the time that physiology in England was being reborn through the activities of Sharpey. No separate chair of physiology existed in England until 1874, when Sharpey, who had been professor of anatomy and physiology at University College, London, was succeeded by Burdon-Sanderson as the first professor of physiology. Since that date specialization had made notable strides. Whereas in the sixties the student's chief study was anatomy, there had now grown up special courses of instruction in the preliminary sciences and in anatomy, neurology, histology, embryology, organic chemistry, physical chemistry, physiology, experimental physiology, biochemistry, and pharmacology, each with its professor or special teacher. Herein lay the great dilemma of the medical curriculum, the solution of which, the speaker contended, was to be sought in two directions: first, in an extensive modification of the present system of examination, and secondly, in the exercise of a sympathetic understanding by the specialist teacher of the difficulties of students, and a proper perspective of the relation of his own subject to the requirements of the curriculum as a whole. It was impossible, and perhaps undesirable, at the present time to frame instruction in physiology so as to equip adequately the ordinary medical student to proceed directly to the prosecution of research in any of its branches, but since one of the main objects of instruction was to enable the latest results of physiological investigation to be utilized in the clinic, it seemed that a good way of effecting this would be for workers specially trained in physiological methods to enter the staff of clinical units where facilities for research work were at hand. As regards the relation of the exact sciences to physiology, their value had been immense. More particularly, mathematics and mathematical physics had exercised their influence by bringing the accurate experimental and intellectual methods of physics to bear on the construction and use of the numerous instruments employed, and by furnishing the means for evolving generalizations out of experimental data. Owing, however, to the complicated conditions involved in physiological experiment, as compared with the relatively simple conditions of purely physical experiment, it had been found impossible up to the present to avoid a considerable margin of variation in the results of many physiological experiments. By regarding these, however, as "chance" variations, considerable help had been obtained by the application of the theory of errors, based on the theory of probability. Research by such statistical methods had proved a useful method of investigation. An elementary deduction to be drawn from the consideration of these facts was that where only a few experiments of any kind were performed, important conclusions could not be regarded as established unless it could be shown that the conditions were so controlled, and the accuracy of the observations so high, that the sum of individual "chance" variations was bound to be small. Observation of this precaution, the speaker said, would reduce the bulk of physiological literature very materially, with a corresponding improvement in its quality. The contribution of pure physics and chemistry in the development of physiology was then touched upon, reference being specially made to the rich harvest already reaped through the union of chemistry and physiology in the form of biochemistry. Turning to the relation of anatomy to physiology, Professor Lovatt Evans recalled the fact that when physiology separated from anatomy it took with it all those dynamical problems which concerned function, leaving anatomy little but the dry bones. The consequent stationary condition of anatomy during the last decades of the nineteenth century was little relieved by the subsequent incorporation of anthropology and embryology. Signs, however, were now wanting of the growth of a more living and scientific type of anatomy, and a prospect that the artificial line of

demeantation between anatomy and physiology would be obliterated. With regard to the philosophical aspect of physiology, it was contended that there should be no misapprehension as to the nature of the assistance which physiology derived from the exact sciences. They in no way helped towards an explanation of the phenomena of life, they merely enabled them to be described more accurately. What life was would remain a mystery for all time, and the views of each on that subject would depend largely on individual temperament and physiological make-up. Physiologists, in attempting to know what life was, had attempted too much. A new standpoint was needed, and it would seem that the idea of adaptation might advantageously be accepted by physiology as its basic principle, just as the chemist accepted the conservation of matter and the physicist the conservation of energy. Not a definition of what life was, but a brief statement of its way, was valuable and stimulating. Regarding the organism and its environment as one, it would be perceived that life was conserved by adaptation, and this conception could not fail to be of value alike to general biology, to physiology, and perhaps most of all to pathology. For there was no fact in biology, pathology, or therapeutics which might not be profitably viewed from this fundamental physiological standpoint.

The Psychology of Education

In the Section of Psychology the application of this science to education was illustrated by Dr C S Myers, who commented on the clash of evidence regarding the relation between innate ability and "trainability," and concluded that a psychologically effective measurement of improvement and improvableity was very difficult. He distinguished between the mechanical repetitive "practice" of an innate ability, which led to precocious ripening, and the higher "training," which produced the best attitude, technique, and style. He also drew distinctions between general, group, and special educabilities. Professor C W Valentine reported experimental investigations into the psychology of early childhood, which tended to rebut the view that later childhood could be interpreted in terms of adult experience, such a study afforded the only reliable evidence as to what was innate in human nature. The supposed stable reflexes had been found to be very variable in the same child on different days, and could not, therefore, be used as the basis for standard tests. Watson's demonstration of the absence of innate fear appeared to be unreliable. Mr P M Earle and Dr A. Macrao dealt at length with the principles, methods, and tests of vocational guidance. In the Section of Educational Science, educational and child guidance clinics formed the subject of papers by Messrs W Boyd and R H Crowler, and Miss M Drummond.

The Nature of Skill

In his presidential address in the Section of Psychology, Professor Peir suggested that for the purposes of scientific discussion skill might be defined as "an integration of well adjusted performances." The aptitude for a particular form of skill might be regarded as based upon well-coordinated reflexes, instinctive tendencies, adapted habits, and the power of "patterning." The physiological conception of skill as consisting entirely of an integration of "conditioned reflexes" could not be regarded as completely satisfying. To ensure the certain conditioning of a reflex the control of external surroundings must be complete, whereas skill typically showed itself in the rapid adjustment to a changing environment and to unforeseen conditions. Even in such a dominantly reflex event as the maintenance of posture, the matter might be partly controlled by consciousness, by taking thought we could improve balance, assume different types of it, and even plan balances in advance. With regard to instincts, their part was probably unimportant. Unlike many animals, man was born unskilled, his skills were acquired, not inherited. But such instincts as those of self-assertion, self-display, and the like might play an important part in impelling him to acquire a skill against material and human obstacles. Habits, naturally, were important components of any skill, they ensured adequate adaptation, and where the conditions were complicated the habitual movements

interacted so that the whole was more than the sum of its parts. Skill, however, was not a mere collection of habits. The essential characteristic of skill was, according to Professor Peir, the ability to integrate responses and, in the highest skills, to substitute, if necessary, one type of integrated response for another, whereas habits were acquired specific responses to specific situations. "Patterning," which objectively considered might be said to be the arranging of human movements in an integrated order in time and space, also played an important part in skill, moreover, it formed the basis of individuality in performance, the particular integrations of part-actions into wholes expressing the individuality of the performer. The power of patterning might be partly acquired, partly innate, and genius in skill might be exhibited in the ability to produce novel patterns. In the matter of classification Professor Peir recognized five groups: (1) Collections of imperfectly adapted responses. This class included the skill of most labourers and workers in the semi-skilled trades. (2) Perfectly adapted responses which did not exhibit personality. Such were the movements on parade of the perfectly drilled soldier. Military skill of this type might be compared with the skill which would result in industry if a stereotyped series of actions, however efficient, was rigidly applied. Its advantages and defects were clear in military organization. (3) Responses resembling habits, but less specific and automatic. Such responses were exemplified in sport when rapid, delicately effective complex adjustment was being made towards the surface upon which the player was moving—as, for example, hard and grass tennis courts. (4) Responses similar to the last, but exhibiting in their totality a pattern characteristic of the individual. (5) Creative skill, whether unconsciously exhibited or the result of deliberate analysis—inventive creation—more often exhibited in the world of art, but no less desirable in that of industry. With regard to the relation between intelligence and skill, it had been concluded by some writers that there was no general capacity, no "motor type" of person, and that vocational tests for ability in any performance gave valid results only when the test performance was identical with that for which the test was being administered. These conclusions, however, had been based on tests concerned with simple motor abilities. Another method of attacking the problem was to set it in the form of the transfer of training. Subjects were intensively trained in some skilled activity until their curves of practice showed a marked rise over a fairly long period. It was then observed whether the ability gained was transferred to related performances. The results of tests of this kind varied with the attitude of the subject experimented upon. He might regard the test as a mere mechanical performance devoid of interest, or the test might be so planned that he was able to take a sentimental interest in it—and it was generally held that transfer largely depended on the formation of a sentiment. The evidence seemed to show that the problem of transfer might be divided into two parts: (a) transfer resulting from the exercise of some particular function, and (b) transfer resulting from extension of attitudes, sentiments, ideals, or knowledge of methods, where the particular function trained was the vehicle of these mental powers. The former was rare, the latter could undoubtedly occur, but only under suitable educational conditions, and the automatic occurrence of transfer could not now be assumed by anyone conversant with the facts.

Mental Analysis and Psychotherapy

Dr William Brown discussed the place of mental analysis in psychological investigation. He suggested that the term psycho-analysis should be kept for Freudian doctrine, and that the investigation involved in obtaining the material for theorizing and new facts in psychology should be entitled "deep analysis," implying analysis of the depths of the mind, this analysis would be performed by different investigators and by the same person on different occasions. It was necessary to distinguish between the therapeutic effects of analysis and the theoretical conclusions that might be drawn from its results. The cure of the patient's illness was due to underlying uncontrolled mental factors being brought into the

consciousness, and coming under the sway of the conscious control. The patient recalled episodes of earlier life, re-living experiences of childhood, this gave him the power to control the symptoms though the mental causes of his recovery might remain obscure. Freud's Oedipus complex in the sexual sense was too narrow, though it was true that the general reactions of the child to its father and mother were of fundamental importance for its future life and character. The self-knowledge obtained by the patient as the result of such analysis was different from the other factor in the cure—namely, the re-living of the past with great vividness, which resulted in the removal of repression and the conferring of re-association. Self-knowledge, the patient's becoming aware of the cause of his illness and not being merely told it, was of very great importance, though the patient did not always realize how it came about that he had been ill and was now getting better. Further research was necessary in this respect by workers of independent character who were prepared to draw conclusions for themselves from the facts they discovered. In addition to the factors of re-living and acquiring self-knowledge there was the general factor of transference to the analyst of the mental attitude referred in early life to the parents and others, there was also the suggestibility of the patient as regards the analyst, suggestion and transference not being wholly identical terms. Thus a patient analysed by a Freudian tended to shape his views accordingly, losing his power of criticism unless he resumed after each analysis his own independence of thought and critical ability. There was need for closer co-operation between the practitioners of differing psychological schools if progress was to be more rapid in the future. Mental analysis must be followed by mental reconstruction, the patient being encouraged in a Socratic form of instruction to discuss his problems, to debate alternative courses, and eventually to make his own decision with the help of his adviser, though not under his control. With the gain of self-knowledge the patient became less emotional as a rule without losing actual force. Analysis seemed to be educative, not only of intellect and reaction to life, but also of the primitive instincts, which became more manageable. The personality became freed from fixations on past experiences, from the tendency to regress to earlier attitudes, and from "compensations" and other forms of self-deception.

Normal Psychology in the Medical Curriculum

A committee, of which Dr William Brown was chairman, furnished a report on the place of normal psychology in the medical curriculum. It was stated that a questionnaire had been circulated to all medical schools in the British Isles and the Dominions, inquiring what facilities were offered to medical students for acquiring a knowledge of normal psychology, and whether the instruction should be optional or compulsory. It was reported that thirteen schools in the British Isles offered no facilities, eight had optional courses, and in five there were compulsory ones. Most schools in the Dominions had courses, sometimes, apparently, of an extensive nature. Such instruction in normal psychology was placed, as a rule, in the pre-clinical or preliminary clinical years, a series of lectures being given with occasionally some experimental work. The majority of the opinions received in answer to the questionnaire favoured the provision of optional instruction in this subject. The committee reported, therefore, that, in its opinion, facilities should be available in every medical school for instruction in normal psychology in the pre-clinical years, preferably the second one. There should be not less than ten and not more than twenty lectures, and wherever possible about ten two-hour sessions in experimental psychology. The course should be compulsory, and the instruction have special reference to medico-psychological facts and problems, this would give a working basis for subsequent lectures in morbid psychology, which should be considered a necessary part of the general instruction in psychiatry. The findings of the committee are to be circulated to those medical schools which replied to the questionnaire.

Other Psychological Subjects

Mr E R Clarke discussed the mental tests of Binet and the group tests. He concluded that in both cases there was an additional factor of variation, which was either an extra emotional reaction called up in the young child by the strangeness of the situation, or was the result of the varying of environmental influences during the initial stages of learning, which were eliminated later when the child settled down to its real place in the scholastic scheme. In the Binet test this time came after the age of 6, and, in the group tests, after the thirteenth year, only then could the tests be used as sound diagnostic technique. Dr R D Gillespie considered the relation of the size of the family to psychoneuroses, and concluded that the effects of place in family in producing psychoneuroses were probably psychological. The "only child" might be nervous when young, but did not tend to grow up into a particularly nervous adult. While the eldest and youngest members of a large family were more likely to be intellectually distinguished, there was a corresponding liability to some mental defect or disease. Dr S Dawson, in a paper on "Dullness and disease," reported a comparison of the average intelligence ratios of groups of children suffering from various ailments with those of their brothers and sisters, and with those of the same patients subsequently. The investigation showed that most ailments had little or no appreciable effect on intelligence, though some—such as encephalitis lethargica and epilepsy—were not only associated with mental abnormality, but actually produced it. Diseases of the nervous system which were limited to the spinal cord did not appear to affect the intelligence.

Signature of the Vas Deferens

In the Section of Zoology the committee (Dr F A E Crew, Mr J T Cunningham, and Professor J S Huxley) for the experimental investigation of the effects of vasoligation on the seminal tubules and interstitial tissue of mammalian testes presented a further report, their previous one was noticed in the *Journal* of September 10th, 1927 (p 460). The new experiments related in part to the grafting of rat testes, from which little success had been obtained. Attention had, however, been more particularly devoted to the effect of an artificially raised temperature, it was found that by exposing the scrotum to a temperature equal to that of the interior of the animal's abdomen the course of disorganization in the seminal epithelium could be traced in detail. It was noted that the normal condition persisted longer in the peripheral tubules than in the more internal ones, and that disorganization in the individual tubule commenced in the internal layers of cells next to the lumen and proceeded centrifugally.

Various Topics of Medical Interest

Dr R R Rusk dealt with the technique and organization of educational research, and considered "mass" as contrasted with "individual" methods. In describing the organization of research he mentioned the necessity for having a bureau or institute to assist and inspire individual workers, organize co-operative investigation, collect data, record failures, and collate and disseminate reports. Mr W Fitzgerald contributed a critical discussion of the population problem of South Africa. Miss D Strangeways reported the results of a comparative study of leucocytes and fibroblasts cultivated *in vitro*. She found that transformed leucocytes differed from fibroblasts in their smaller nucleoplasmic ratio, in certain important cytological features, and in the character of their intracellular and amoeboid movements. Professor J H Ashworth spoke on the distribution of anopholes in Scotland with reference to the existence of malaria. Dr D N Buchanan reported a series of experiments which indicated that hypnotism might find a new scope for utility in enabling students to pass examinations. Visual imagery was thus increased and the power of musical improvisation was enhanced. Stammering, and drug or alcohol obsessions, could also be cured by this means. Surgical operations had been successfully performed under hypnosis. Functional blindness or deafness might similarly be permanently cured.

British Medical Journal.

SATURDAY, SEPTEMBER 15TH, 1928.

THE FALLING BIRTH RATE

THE subject chosen for discussion in the Section of Medical Sociology at the Annual Meeting of the British Medical Association at Cardiff was 'The falling birth rate.' On August 18th (p. 310) there appeared a summary of the discussion and at page 477 this week we print in full the opening papers. These papers are of exceptional interest as indeed was the greater part of the debate to which they gave rise, in spite of the fact that those who took part in it, losing, perhaps, a little sense of proportion in their zeal for a cause, persisted in confusing the subject with that which is now commonly described as 'birth control.' It is, of course, the object of this particular Section of the Annual Meeting to consider matters which are largely non-medical in their bearings and on the present occasion care was taken to secure an adequate presentation of the subject of the falling birth rate from the economic and biological aspects, as well as from the medical standpoint. This disclosed a considerable measure of disagreement, perhaps not quite irreconcilable, among the openers of the discussion, and the conclusions of those who read these pronouncements, or who were present at the sectional meeting, may reasonably be that the complexities of the subject are very great, that the actual data for forming a rational judgment are confused or meagre, and that only to a small extent can it be regarded as a medical question.

One of the most valuable contributions to the discussion was Sir Thomas Horder's argument—his demonstration, indeed—that the population problem overlaps very little the actual activities of the medical practitioner, whether his work is concerned mainly with the individual when sick, or with the prevention of disease. The question of over-population or under-population lies almost wholly outside the sphere of the medical profession as such. This is an important matter, for indications have not been wanting that both the profession and the public are in danger of confusing their functions in certain fields of public health and welfare, and of asking and expecting more than should be sought or required. In some of these fields the medical profession has special competence, and therefore upon it lies special responsibility. Its members individually and its societies collectively are especially qualified in these cases to advise the community, and must seek to initiate sane and efficient action. But the profession has no right to demand that the public shall accept its views, the final responsibility for action or inaction rests not with it, but with the public, which has complete liberty, after seeking what advice it wills, to take whatever action it chooses. Similarly, the community has no right to demand or expect guidance from the medical profession on matters which though it may be competent to give advice in individual cases when they may arise, are in their broader aspects not strictly medical. In such matters the public must seek advice elsewhere. The population question is one of these matters. From Sir William Petty's remarkable *Essays on Political Arithmetic* and Daniel Defoe's extraordinary *Essay upon Projects* in the last quarter of the seventeenth

century, through the work of the Rev. Thomas Malthus and Sir Francis Galton to our own day, it has always been first the economist, and later the biologist, whose function it has been to elucidate the main problems in this field. The biologist rather than the economist seems likely to be the more valuable helper in the immediate future, but ethical, sociological, and even political questions may legitimately, or must necessarily, arise also. It is true that, as in the case of Sir William Petty, who was himself a doctor of medicine and professor of anatomy in the University of Oxford, members of the medical profession will make incursions into these alien or cognate fields of observation, and many doctors will be interested therein; but their opportunity or authority for making contributions thereto, specifically as medical men, is quite restricted.

Viewing the problem of the falling birth rate from these wider aspects, the discussion at the Cardiff Annual Meeting would seem to tend towards the establishment of certain propositions as at least probable. There is a law of population growth which occurs in cycles, following in the main a curve of a definite type. The birth rate is falling now because we are at the end of such a cycle and it will not again rise until those factors which are at present overriding the inherent tendency to increase are recognized and removed. Density is one of the controlling factors, but the estimate of density should be applied not only to a country, but to restricted localities, and must be judged, not by total numbers, but by the relation of such numbers to resource and opportunity. Voluntary control of conception has undoubtedly prevented the birth of many individual babies, but it may be doubted whether this has appreciably affected the crude birth rate or population growth cycle. It is a devastating thought that as Dr. Crew put it very wittily, the immigration of an Irishman into Glasgow may of itself prevent the birth of a Scotsman! Further there is no true ground for the impression that the people of any country can be divided into their distinct breeds corresponding to their social status, some of which are biologically more fit than others. There are biologically and socially unfit persons in some abundance, and it is fortunate that, broadly speaking, these tend to segregate themselves so that it becomes more easy to deal with them and less likely that their offspring will survive to maturity, but the suggestion that the relatively unfit are more abundant among the socially lower is not necessarily valid. If any safe and effective methods of conception control were widely known, they would, in fact, be practised, apart from other considerations only by the more prudent of any class, and to restrict further the birth rate among the better artisan and working population would scarcely be a social advantage and certainly not a biological gain. So far the emerging science of group biology is helping to throw light on these problems, both directly and by its reactions on economics. But dogmatism is not yet justified, and among the matters into which it is still more urgent to inquire are the effect on conduct and habit generally of a widespread dissociation of sexual gratification from parental responsibility and certain other consequences of childless marriages and of very small families.

Are there then, no specifically medical points to which attention should be directed in this connexion? Certainly there are such points, but very few seem as yet to have become evident. It is clearly the duty of a medical man to advise individual patients as to the necessity or desirability of avoiding or of limiting

pregnancy It is equally clear that it may be his duty to advise or instruct patients about the technique of more or less effective methods of avoiding conception. There seems to be no reason why he should refrain from giving such advice or instruction, even in cases in which potential parents have made up their minds to avoid conception on non medical grounds. But there are at least two important questions, at present admittedly not decided, which he ought to bear in mind before giving his opinion, and which those who are interested in the subject from other aspects may properly ask the medical profession to attempt to answer. One of these is Can any, even the best, of the methods used lead to harmful results in the form of cervicitis or other physical disease or disorder? Lady Barrett, in her opening paper, states that she has found these to result frequently. The other question is Does the prolonged and frequent use of contraceptive methods tend to produce permanent sterility, apart from the relative infecundity which is necessarily brought about by the postponement of conception to a later age? This latter question is manifestly of great importance, not only in its bearing on individual cases, but on the wider discussion of the subject, and it can be satisfactorily determined only by a somewhat prolonged and difficult systematic and collective investigation by the medical profession.

LONDON WATER.

Pursuing his survey of the historic sources of the water supply of London, Sir Alexander Houston has introduced his annual report for 1927 with an illustrated description of the River Lee—known as Lea in cartography. This stream, rising in the Leagrave Marshes a little to the north of Dunstable and Luton, and drawing its waters from the four counties of Bedford, Hertford, Essex, and Middlesex, is famous for its associations with Izaak Walton. It provides London people with about a quarter of their total water supply. In connexion with the Redbourn chalk springs, which feed extensive watercress beds, reference is made to the too prevalent delusion that watercress—and oysters too—flourish best in polluted waters. The author recalls his bacteriological investigation, made a quarter of a century ago, into the quality of the watercress supplied to the London markets and of the water feeding the beds. He found then that the best watercress came from the purest water. Discussing the more general question of the pollution of rivers, he notes that the introduction of the water carriage system of sewage disposal eliminated objectionable material from the neighbourhood of houses, but produced a highly impure liquid which could only be disposed of by running it into rivers. Thus our proximal gain was our distal loss. The purification of sewage effluents beyond a certain moderate standard is unremunerative. Their sterilization at any reasonable cost is impracticable. Even if sterilization were easy it would not make rivers safe to drink untreated. A river flowing through a populous area receives, besides the effluents proceeding from visible and obvious sewage treatment works, unseen contributions of foul material from many unconsidered quarters. To exclude all these tributaries, by statutory or other measures, from their natural destination, which is the stream draining the valley, would be a Herculean task. It is, in fact, easier and more economic to purify a river after pollution than to prevent it from becoming polluted. The main sources of sewage pollution of the Lee and its tributaries above

the water intakes are at Bishop's Stortford, Harlow, Harpenden, Hertford, Hoddesdon, Luton, Royston, Stevenage, Waltham Abbey, Welwyn, and Wheat hampstead. As examined during 1927, these effluents were all well within the standards suggested by the Royal Commission on Sewage Disposal.

The chlorination of the Thames river water continues, at the rate of 76 million gallons daily. In 1927 Staines aqueduct water showed *B. coli* absent from 100 c.c.m. in 81 per cent of samples, Hampton water in 56.1 per cent, and Staines and Hampton water combined in 66.8 per cent. The corresponding figures for filtered waters were at Kempton Park *B. coli* absent from 100 c.c.m. in 83.4 per cent of samples, at Sunbury in 77.8 per cent, at Grand Junction in 75.0 per cent, and at West Middlesex in 72.0 per cent. In the chlorination of the New River, of 122 chlorinated samples collected at Wood Green 89.3 per cent showed *B. coli* absent from 100 c.c.m., of 123 chlorinated samples collected at Hornsey 91 per cent showed *B. coli* absent from 100 c.c.m., of 123 chlorinated samples taken at the outlet from the Stoke Newington reservoirs 21.9 per cent only showed *B. coli* absent from 100 c.c.m. This discrepancy is no new feature. Its most probable origin is some adventitious pollution flowing unseen into the water way between Wood Green and the outlet.

The storage reservoirs which supply London constitute a chain of forty-nine lakes which, taken together, cover 2,700 acres and hold 20,000 million gallons of water. The improvement produced in so great a body of water by dilution and lapse of time amounts to a very substantial security. The condition of this stored water, in Sir Alexander Houston's view, constitutes the pulse of the metropolitan supply, and he has modified the work of water examination in order to throw its qualities into prominence. Lambeth (Molesey) stored water contained *B. coli* in 100 c.c.m. in only 39.1 per cent of samples, as contrasted with raw Thames water, which contained *B. coli* in 0.1 c.c.m. in 50 per cent of samples. The Molesey stored water was 1,000 times better than the raw water of the river. The bacterial improvement is shown in the report as a percentage reduction for various reservoirs in tabular form. In plain language, it would seem to be less risky to drink fifty pints of stored water than one ounce of the native Thames.

The Barn Elms experiment has now been in progress for forty months. It consists in comparing the results of (a) filtration at very high speed without coagulant through a primary sand filter, followed by filtration more rapidly than normal, but not at very high speed, through a secondary sand filter, with (b) ordinary once through slow sand filtration. As photographs display, method (a) reduces diatomaceous and algal growths. In one pair of photographs the field before filtration is filled with fragillaria, while the field after filtration is free. In general, the results of the forty months' experimental working are summarized as follows: bacteriologically, the final product of (a) is as good on the average as (b), (a) has more freedom than (b) from algal troubles and from those caused by an excess of suspended matters, (a) has a much greater output than (b) of water per acre of filtration area, allowing for the space covered by the primary filters, per unit of time. At the Walton works, which were opened in July, 1926, the method of double filtration, experimental at Barn Elms, is put into practical operation. It is preceded by storage and followed by chlorination. The following percentages of samples containing no *B. coli* in 100 c.c.m. were obtained in 1927: raw river water

0.4 stored water 20.2, mixed primary filtrates 36.4, mixed secondary filtrates 74.5, chlorinated water 96.4. These figures are good and tell their own tale. The primary filters were worked, without a coagulant, at the high speed of 119.7 gallons per square foot per hour, and the secondary filters at 5.1 gallons per square foot per hour.

Under the title "Search for Pathogenic Microbes in Water" an account is given of a "semi-positive" method for isolating the paratyphoid bacillus from water. For the treatment of a green colour which appeared in the West Stoke Newington reservoir chlorination was found to give better results than dosage with copper sulphate. The presence of leptospiral organisms in the water is again referred to. Two years ago pathogenic leptospirae were found in the Deptford Garden Well. In 1927 frequent cultures of the London waters were made for leptospira. In the New River leptospirae were numerous before chlorination, after chlorination none could be found. In seven instances the organisms were pathogenic. Sir Alexander Houston expresses the view that, since leptospirae are common in natural waters, their presence in a water which happens to be associated with an outbreak of spirochaetosis should not be accepted as implicating the water without some clear evidence—such, for example, as a high incidence of the disease among consumers of the supply in question combined with a low incidence among others.

CONVALESCENT SERUM IN POLIOMYELITIS

THE recent outbreaks of epidemic poliomyelitis in Rumania, Hungary, and Germany, particularly at Leipzig and Chemnitz, and in the United States (Massachusetts and California), have focused attention on the methods of prevention and treatment of this disease. In a recent paper,¹ written in collaboration with Dr. Fred W. Stewart, Professor Simon Flexner states that studies on immunity and specific therapy in connexion with epidemic poliomyelitis have been resumed at the Rockefeller Institute. Experiments on the monkey, the only animal which is susceptible to epidemic poliomyelitis, showed that if convalescent serum was given intravenously about twenty-four hours before the intracerebral inoculation of the virus, paralysis did not develop. Although the duration of the immunity thus conferred has yet to be determined, it will probably be found to conform with that already fixed in other examples of passive immunization—namely, about three or four weeks. Flexner and Stewart suggest that in the event of severe outbreaks of epidemic poliomyelitis convalescent human serum should be given subcutaneously as a prophylactic measure in doses of 10 c.c.m. for young children and 20 c.c.m. for older children and adults, the injection being repeated in four or six weeks' time if the epidemic persisted. The therapeutic use of convalescent serum, which was first employed by Netter in 1911 and later by Amoss and Chesney in 1916 on the basis of the experiments of Flexner and Lewis in 1910, but has not hitherto led to any conclusive results, has recently been resumed by E. B. Shaw and H. E. Thelander,² who record their observations on 81 patients with acute poliomyelitis, of whom 43 received intramuscular injections of convalescent serum during the active stage of the disease. Persistent paralysis developed in no more than 13 of these to whom treatment was given late in the febrile stage, while of 38 untreated patients 33 showed residual permanent paralysis. The authors' conclusions are as follows:

(1) Intramuscular injection of convalescent serum is of distinct value in the treatment of poliomyelitis. (2) The effectiveness of such treatment depends on early diagnosis and the administration of sufficiently large, and if necessary repeated, doses of potent serum. (3) Owing to its safety and simplicity the method can be used in doubtful cases without waiting for confirmatory evidence. (4) It is very desirable that stores of pooled convalescent serum should be made available for general use, and particularly before the outbreak of actual epidemics. A still more important paper is that of Drs. W. Lloyd Aycock and Eliot H. Luther³ of Boston, on 106 cases of pre-paralytic poliomyelitis in which convalescent serum was used. These authors maintain that poliomyelitis can be diagnosed during its pre-paralytic stage, which usually lasts three days, by signs and symptoms of meningeal involvement, especially nuchal rigidity, though this is not so marked as that usually found in meningitis. Each patient was given two intraspinal injections of serum at twenty-four-hour intervals, and one intravenous dose when first seen. One patient who was treated on the second day of disease subsequently developed fatal paralysis, but the average total paralysis in these cases was only 19, as compared with 69.3 in 482 untreated cases, and only 5.7 per cent. of the treated cases developed paralysis, as compared with 46 per cent. of the untreated group. It is noteworthy that in all the cases treated by convalescent serum the degree of paralysis was estimated by the orthopaedic staff of the Harvard Infantile Paralysis Commission. Many of the patients who were at first thought not to have any paralysis were found by the specialists to have considerable muscular weakness. The proportion of patients, therefore, in the series who were classified as paralysed is not comparable with the proportion in other series of cases in which no expert examination was made.

TALK AND WORK AT GENEVA.

THE League of Nations (writes our correspondent at Geneva) appears to have talked itself out. More than once during the present session of the Assembly the meetings have closed prematurely owing to the lack of orators. The annual and supplementary reports of the Council—huge documents covering every department of the work of the League—were brought forward for discussion by the Assembly, and no one rose to discuss them. Even the committee which is concerned with the technical organizations of the League, including the International Health Office, when it gathered for a meeting which was expected to last three hours, rose at the end of ten minutes. The explanation of this dumbness which has settled upon the talking-shop of the world is that the Assembly, having reached its ninth annual session, is becoming stereotyped. About the earlier sessions there was an air of excitement and expectancy. It was felt that anything might happen. It is now clear that nothing will happen beyond the utterance of amiable platitudes—not that these are without their value. The initiative is passing from the debating chamber to the secretariat and its numerous accessory organizations. "Westminster" is handing over the sceptre to "Whitehall." Another impression which, with more regret, one derives from the present Assembly is that the English-speaking nations—that is, the British Empire—are surrendering their pre-eminence at Geneva to the French-speaking. Day after day passes, and scarcely a word of English is heard in the Assembly, except by way of interpretation. The La in nations have become the directing force on the political side of the League's activities, and the Scandinavian nations on the moral and social

¹ *Journ. Amer. Med. Assoc.* August 11th 1928 p. 383.

² *Ibid.* June 16th 1928 p. 123.

³ *Journ. Amer. Med. Assoc.* August 11th p. 387.

side, while the British Empire accepts a passive or watching role, and Germany still feels herself something of a stranger in these councils. The growth in size and importance of the Health Organization of the League is a more encouraging feature of the international situation. If the test of the value and activity of an organization be the amount of money expended upon it, then the Health Organization's far and away the most important of the dozen or more special organizations of the League. Its expenditure last year amounted to just upon one and a half million Swiss francs, or about £60,000, not entirely contributed from League funds, however, for the Rockefeller Foundation provides more than one-third of this sum. If the League, on its political side, should cease to exist, the Health Organization would remain as a vital necessity of the peoples, and would itself go far to preserve the newly created international amity. Some of the most recent enterprises of the organization illustrate the vigour and initiative with which the health work is being pursued. There has lately been, for example, an interchange of health officers for a study of the problems of rural hygiene, this began in May last in the kingdom of the Serbs, Croats, and Slovenes, and terminated in Geneva at the end of July. The twenty participants, from eighteen countries, visited the rural districts of six European countries, and made a comparative study of rural housing, water and milk supplies, sewerage and sewage disposal, public health and medical organization, and other matters. An interchange of health officers in Italy has just begun, and will continue until November. Representatives of about twenty countries are taking part in this study tour, which is to embrace all aspects of public health enterprise under Italian rule. Another event of the summer has been a conference on malaria, which has drawn up a list of subjects for further international investigation, among them the subject of housing in relation to malaria, and of the species of mosquito concerned in the transmission of malaria in Europe and in the United States respectively. This conference also recommended that the value of plasmochin and quiniostovarsol in the treatment of malaria should be studied in certain countries, including Central America, Germany, and India, while some other experimental studies designed to increase the knowledge of the treatment of the disease will be entrusted to three groups of laboratories—one group in Germany and Italy, another in British India and the Federated Malay States, and the third in Spain and Algeria. Other recent conferences have included one at Copenhagen on the sero-diagnosis of syphilis, for which thirty-eight experts assembled, a meeting of the small-pox and vaccination commission, to study post-vaccinal encephalitis as an international problem, and a meeting of a subcommittee of experts charged with the study of radiotherapy in the treatment of cancer. This last body set out certain questions for further study, which is now proceeding, these include the questions of propaganda among medical men and the general public in order to ensure the early discovery and the early and correct treatment of cancer of the uterus, of an increase in the number of consultation centres, and of the radiotherapeutical equipment of clinics. The subcommittee also noted as a subject for inquiry the available supplies of radium and the need for an authoritative opinion as to the advantages and drawbacks of distributing radium or radium emanation to hospitals and individual practitioners. These and several other activities are of quite recent origin, and are set out in the supplementary report of the Council, which covers the period since May last. It is evident that, if the tongue of the League is less busy than formerly, its hands, in one sphere of endeavour at least, are busily working, and to some purpose.

THE MECHANICS OF THE DIGESTIVE TRACT

There are many problems in physiology and pathology which a knowledge of mechanics helps to solve, and the trained physicist or engineer can very often make valuable suggestions when the facts of such phenomena as peristalsis or muscular contraction are put before him. These remarks are stimulated by the appearance of a second edition of *The Mechanics of the Digestive Tract*,¹ by Dr. Walter C. Alvarez, in which the author has considerably amplified the theories he first put forward some years ago. He bases his solution of many of the problems of gastro-enterology on the "gradient," defined in general terms as "a gradation, usually in some attribute or state or force or activity, which is to be found between certain limits in space or time." In the heart, for example, it is well known that the beat follows a gradient of rhythmicity from sinus to ventricle, that is, the isolated auricle, near the great veins, will beat faster than the ventricle. In the ureter also the fastest rate of rhythmic contraction is often to be found in the plexus of this tissue nearest the kidney. Alvarez suggests that there may be a physiological law whereby the direction of transport of material in a tubular organ depends on gradients of rhythm, tone, and irritability. The gradient in the rate of rhythmic contraction can be shown to exist in the alimentary canal in the rabbit: the rate of contraction in the duodenum is about twenty per minute, compared with ten in the ileum. Side by side with this gradient of rhythm there appears to be a metabolic gradient, and experiments have shown that the production of CO₂ and the amount of oxygen used by equal weights of muscle from different regions of the alimentary canal have a definite gradation from duodenum to colon. There is also some evidence to show that the catalase content of the intestinal muscle has a gradient closely parallel to that of rhythm and metabolic activity. Investigating a patient who had a jejunal fistula, Alvarez found that there was also a gradient in the "pulling force" exerted by different parts of the bowel on balloons, so that there appears to be a "gradient of propulsive force along the bowel much like that in a pipe line." With this gradient notion as the fundamental principle Alvarez works out in some detail his conceptions of the mechanics of the different parts of the alimentary tract, returning to the practical applications of the idea at the end of the book. If it be true that a downward gradient is of value in health, it follows as a corollary, he says, that upsets in it should produce symptoms of disease. Such upsets have, in fact, been observed in animals with disturbances in the various gradients, but it is not possible to speak with certainty in the case of man, although the evidence is suggestive. Irritating lesions of the alimentary tract may affect the metabolic gradient, an increase in metabolic rate of any part of the alimentary tract leads to a more rapid rate of rhythmic contraction, and it is well known that inflammation increases the irritability and tone of the intestine. When diseased conditions are under consideration it should be noted that there is a great difference in the hardness of muscle taken from various parts of the alimentary canal. The muscle in the duodenum, for example, is much more sensitive to adverse conditions than is the muscle in the ileum, and the muscle of the colon is more hardy than that of the small bowel. The influence of toxins on the alimentary canal will therefore tend to lower the effectiveness of the upper end with a corresponding rise in that of the lower, so that the gradient is reversed. This idea of the reversal or flattening of the gradient can be used to explain the loss of appetite, disgust for food, nausea, and vomiting seen in infectious disease and asthenic states, for in such

¹ *The Mechanics of the Digestive Tract*. By Walter C. Alvarez. M.D. Second edition. London: William Heinemann (Medical Books) Ltd. 1928. (6 x 9½ pp. xix + 477. 100 figures. 31s. 6d. net.)

cases a patent pylorus and good peristaltic waves can often be seen, ruling out a simple local mechanical explanation. Alvarez's ideas are not easy to follow by those whose notion of a gradient is confined to a vague idea of a hill, but in the sense in which it is used by the hydraulic engineer the term has much to commend it.

CHRISTIAN SCIENCE AND THE DOCTOR

MEDICAL men who read the daily newspapers are probably aware that a schism has arisen in Christian Science ranks. The Christian Science Parent Church, some four years old, is considerably younger than the other member of the family, the Church of Christ Scientist. The word "parent" is a little confusing, therefore, but it will be recalled that W. S. Gilbert raised much the same question in the case of the immortal Iolanthe, and some years ago (unless our memory has played us false) there used to be a standing debate on whether the hen was the mother of the egg or the egg the mother of the hen. It is not for us to comment on the heresy hunt which has started, but there is some interest in one of the points at issue—namely, the relationship of Christian Science teaching and practice to the medical profession. From literature sent to us by Mr. John A. Dittmore, contributing editor of the *Christian Science Hatchman*, it appears that the Parent Church, founded by Mrs. Annie C. Bill in 1924, is convinced that the time has arrived for some recognition of the doctor by the Christian Scientist, or of the physician by the metaphysician, as Mrs. Bill prefers to call him. Both Churches profess allegiance to the doctrines of Mary Baker Eddy, but the Parent Church produces ingenious arguments to show that the soundness of the faith was preparing the way for the recognition by her disciples of medical aid as an adjuvant of faith, when death ended the sufferings for which she had been compelled to resort to injections of morphine. In the early stages of evangelization—so the argument runs—it was necessary to forewear medical methods in treating disease in order to emphasize the importance of "methods of mind." But the distressing fact remained that the majority of mankind rested its hope of recovery upon "materia medica," and since one of Mrs. Eddy's axioms was that "the greater controls the lesser," it became easy to see that her sufferings were caused mainly by the majority of false beliefs of mankind. Vain was the dismay of Mrs. Eddy's students, vain their attempt to hide the doctor's visits, or prevent their leader's resort to the drug. While the majority of people continued to hold wrong beliefs Mrs. Eddy could not escape from suffering. The time was ripe, therefore, for the second period of the crusade, the "destruction of the degenerate element of wrong beliefs in which all disease originates." And so Mrs. Eddy took to morphine. The Parent Church alleges, with some show of reason, that the other group is illogical in its attitude towards drugs. Since all is mind, and there is no matter, it is plain that drugs are only a part of mind, or parts of the phenomena of the human mind. Mrs. Eddy was justified, therefore, in the intelligent utilization of the "vehicle" of the human mind operating in that special mode. But the older type of Christian Scientist—the argument proceeds—is not justified in building hospitals, in miscalling them "benevolent sanatoriums," in preparing for the reception of diseased conditions, while all the time students of the cult are being taught that "to permit disease to be present in the thought must bring it into the experience of the individual." Far better that he should come over to the Parent Church, and invite the aid of the doctor in destroying the degenerate element of wrong belief by means of the immaterial vehicle, materia medica. It remains to be seen how far the physician will advance to meet the proffered embrocades of the meta-

physician, and co-operate in "healing disease on the highest moral and spiritual basis," so that "Christian Science will be universally acknowledged to have brought to humanity the missing healing element of psycho mental energy." There is a type of mind within our profession which can discover in Hahnemann the father of rational dosage, and in Gall the father of brain localization for such it may not be too great an effort to regard Mrs. Eddy as the mother of psychotherapeutics. In the meanwhile it is not without significance that there are Christian Scientists today who can allow to the medical practitioner some merit in dealing with disease and it will be interesting to watch the effect of the new by-law of the Parent Church, which renounces commercialism and "financial rivalry with medical specialists."

TULARAEMIA

IN a recent article W. M. Simpson¹ refers to tularaemia as being "in every respect the first American disease," meaning apparently, that it was the first example of a disease first described in America. Although this may not be correct, as Decimus's and other diseases bear witness, it was certainly first observed and its bacteriology and etiology established in the United States of North America, thus Ansel Martin, an ophthalmic surgeon of Arizona, in 1867 reported five cases of human disease ascribed to an infection derived from skinning and dressing jack rabbits, Pearce of Brigham City, Utah, gave the first accurate account of the clinical features of "deer-fly fever," long known to the ranchers, McCoy and Chapin in 1911 isolated a new organism, *Bacterium tularensis* from ground squirrels dead or dying of a "plague-like" epizootic in Tulare County, California, Vale, in 1914, described a case of *B. tularensis* infection of the eye, and, more especially, E. Francis finally correlated these data. He showed that the "plague-like" disease of rodents and the deer-fly fever were both due to the same infection, which he called tularaemia, and that the blood serum of those who had passed through an attack agglutinated *B. tularensis*. The common wood tick (*Dermacentor variator*) infesting wild rabbits and other animals in Montana was shown by Parker and Spencer (1925) to carry the infection, which was transmitted among them hereditarily by the eggs from generation to generation. In the same year Hachiro Obara in Japan recorded a febrile disease transmitted by wild rabbits, which serologically and bacteriologically was proved by Francis and Mayne to be tularaemia. In the meanwhile Ledingham and Fraser (1924) in this country had reviewed the subject in an article on "Tularaemia in man from laboratory infection," of which much evidence was forthcoming in North America, indeed, it appears that most of those who have worked at its bacteriology have paid this penalty. Recently during five months Simpson unearthed 53 cases of tularaemia, and met with one fatal in four days and seven hours, the shortest time on record. He points out that since 1924 there have been 613 authentic cases, and that the disease has a seasonal incidence corresponding with the greatest activity of the wood-ticks and the deer-flies. In an analysis of more than 600 cases he recognizes four types of clinical conditions: (1) *The ulceroglandular*. This the commonest (415 cases) and most important, begins as a papule, which becomes necrotic and is followed by glandular enlargement with nodular lymphangitis like that of sporotrichosis. The onset is sudden, and the disease at first is like severe influenza with delirium. (2) *The oculo-glandular*. Of this form 26 cases have been reported. It starts in the eye, and in 22 instances was unilateral. (3) *The glandular*. The primary lesion in this variety is not obvious, but the lymphatic involvement is the same as in the ulceroglandular

¹ Simpson W. M. *Proc. Staff Meetings of the Mayo Clinic*, 1928, 311, 213.

type (4) *The typhoid* In this there is no obvious primary lesion or glandular implication, it imitates typhoid fever. Most of the laboratory cases are included among the 26 cases coming under this heading, and it has been shown that the micro-organism can penetrate the unbroken skin of guinea pigs and rabbits. The condition may be confused with a number of other infections, such as influenza, typhoid and undulant fevers, and, Simpson remarks, "pathologists have clung to the histo-pathological diagnosis of tuberculosis because of the remarkable similarity in the appearance of the two granulomas." The diagnosis can be made by agglutination reactions, and it is stated in Simpson's paper that the results of treating the acute stage of the disease with immune human serum will form the subject of a further report.

INTERNATIONAL MEDICAL ORGANIZATION

In the Supplementary Report for 1926 and the Annual Report for 1927 the Council of the British Medical Association reviewed the development of an international union of medical organizations designed to promote the interchange of information and ideas connected with the social and political aspects of medical practice. After two years' close observation of the progress of this association the Council decided, mainly on grounds of economy, not to join it. This decision was reversed by the Representative Body at Cardiff after a full and informative discussion on a motion by Dr C. F. Douglas to the following effect: "That the Representative Body is of opinion that the Association should give full support to the Association Professionnelle Internationale des Medecins as a body which affords the medical profession in each country the opportunity to make its contribution towards closer co-operation in all matters of common interest and instructs the Council to take the necessary steps towards full membership." The aim, constitution, and activities of the organization in which the British Medical Association will thus assume the responsibilities of membership are well illustrated by a report of which we publish a condensed translation at page 133 of this week's *Supplement*. The original report is the work of Dr Fernand Decourt, general secretary of the A. P. I. M. (as it is known familiarly), and one of its original founders. We may add that inquiries have already been instituted by the union, not only into the subject of national health insurance, reviewed in this report, but also on the following topics: (1) the constitution and general position at the present time of organizations dealing with medical politics and defence throughout the world, (2) possible methods of co-operation between the A. P. I. M. and the International Labour Office at Geneva, (3) laws regulating medical practice, qualified and unqualified, throughout the countries covered by the A. P. I. M., (4) laws and customs regulating the practice of medical specialties, (5) pharmaceutical services and freedom of prescription in connexion with organized medical services, (6) conditions governing the issue of motor drivers' licences. The results of all these inquiries are, of course, made available for the use of the British Medical Association as a member of the A. P. I. M.

DERMATITIS AMONG BAKERS

BAKER'S dermatitis has long been known to the medical profession—in fact, there is a good clinical description of it in the very first textbook of dermatology ever published, that of Willan, which appeared in 1808, but it has only come into prominence as an industrial disease during the past fourteen years. Since 1917 it has been notifiable, and workers suffering from it are entitled to compensatory allowances. At the recent annual conference of the Amalgamated Union of Operative Bakers and Confectioners it formed the subject of a discussion, a resolution was

passed expressing alarm at the spread of dermatitis among the members, and calling upon the Government and master bakers and millers to protect workers against it. The representatives of the operatives have always contended that the eruption, which is comparable clinically to an attack of eczema, is due to some impurity in the flour, probably introduced for the purpose of bleaching it, and this view found full expression at the recent annual meeting of the union. But this explanation of the disease is challenged by the employers, who affirm that neither of these contentions is well founded, in the first place because officials of the Ministry of Health have reported that baker's dermatitis tends to become less rather than more frequent, and further investigations into its causation, which have already been undertaken by the scientific staff of the Ministry, have conclusively shown that neither bleaching agents nor "improvers" in the flour had anything to do with the incidence of the disease. In addition to the investigations undertaken by Dr Allan Parsons on behalf of the Ministry, Dr Prosser White has made some independent experiments, which have been published in the *British Journal of Dermatology*. It appears that for the most part the patients affected come from small establishments where the work is done by hand, and consequently the hands and arms of the workers are exposed to maceration from long contact with mixtures of flour and water, and where perhaps the facilities for proper cleansing of the skin are somewhat imperfect. In larger establishments, where machinery makes this prolonged exposure to such deleterious influences unnecessary, the disease is quite infrequent. The proper method of dealing with this troublesome affliction, therefore, appears to be the extension of the use of dough mixing machinery, and the provision of proper accommodation and washing facilities for the operatives.

ROYAL SOCIETY OF MEDICINE JOINT DEBATES

THE calendar of the Royal Society of Medicine for the session 1928-29, under the presidency of Lord Dawson of Penn, has just been issued. It has been decided to continue the practice of holding special joint discussions, and at a conference of the presidents and presidents-elect of the various sections, held under the chairmanship of the outgoing President of the Society (Sir James Berry) the following subjects for discussion were agreed upon: (1) Encephalo-myelitis of man and animals (Sections of Comparative Medicine and Neurology) (2) Industrial dermatoses, their causation, recognition, prevention, and treatment (Dermatology, Epidemiology) (3) Post-operative thrombosis (Pathology, Surgery, Obstetrics) (4) Prognosis and treatment of general paralysis of the insane (Psychiatry, Nematology) (5) The indications for, and the results of, splenectomy (Surgery, Medicine) (6) Glanders and kindred diseases (Tropical, Comparative Medicine) (7) Urinary antiseptics (Urology, Pathology, Therapeutics) (8) The necessity for early diagnosis in the treatment of spinal injuries (War, Surgery). The dates of these combined discussions will be settled later, and announced from time to time in the society's diary card.

THE Clinical Congress of the American College of Surgeons will be held in Boston this year from October 8th to 12th. The College has invited the Editor of the *Lancet*, Sir Squire Sprigge, to deliver the Hunterian Oration on the evening of Tuesday, October 9th. The Honorary Fellowship of the body will be conferred upon Sir Squire Sprigge.

THE sixth Lloyd Roberts Lecture has been arranged by the Royal Society of Medicine for Thursday, November 29th, and will be delivered by Sir William Bragg, D.Sc., F.R.S., this year's President of the British Association.

"THE SKULL OF LORD DARNLEY."

BY

H. A. HARRIS, M.B., B.S. LOND.

(From the Institute of Anatomy, University College, London.)

WHEN Sir Arthur Keith, on August 1st, asked me to examine the reputed skull and femur of Lord Darnley I did not know that Professor Pearson's monograph (discussed by him in the *British Medical Journal* of September 8th, at page 456) was already printed. I subjected the skull and femur to radiographic examination, and concluded that neither could

have belonged to Lord Darnley, who was not more than 22 years of age at the time of his death. Furthermore, the lesions of the skull which are reputed to be syphilitic show none of the pathological bone changes associated with the disease. I submitted my report to Sir Arthur Keith on August 12th, and I propose to add nothing to it. However much one may

FIG. 1.—Radiogram of the basi-cranial axis showing the absence of any trace of recent union of the basi-occiput and basi-sphenoid bones.

admire Professor Pearson's vineible patience in the attempt to rehabilitate one of the many red-haired Hussies who have crossed the stage of time, and however much one may be impressed by his well-known partiality for the red-haired section of the community, anatomical truth is not concerned with virtue, morals, or the meretricious wiles of the satellites of the Court.

I append the report which I submitted to Sir Arthur Keith on August 12th, and I suggest that a committee of the Pathological Society be asked to report on the question of whether the lesions of the skull are syphilitic or artefact, for there are still a few pathologists acquainted with the protean manifestations of syphilis. Professor Pearson might perhaps be excused for omitting to submit the skull to the examination of anatomists, for few anatomists know much about the age changes in the skull, but why the help of "a distinguished American pathologist" should have been sought as a diagnostic guide by one working in the precincts of the late Sir William Gowers is beyond me.

REPORT ON THE SKULL AND FEMUR OF LORD DARNLEY.

A. THE SKULL.

I. Gross Appearance

The skull is that of a male with a cranial capacity of about 1,350 c.c. and is strikingly low in the brow. The auricular height is about 2 to 2.5 cm. below the average for British skulls. The thickness of the skull with the appearance of the section suggests no pathological condition, and is well within normal anatomical limits for a skull in the third or fourth decade.

II. Suture Union

All the sutures are open except (1) the sphenoidal suture, (2) the sagittal suture.

1. *The Sphenoidal Suture*.—Both to naked-eye examination on the sectioned skull and to radiographic examination there is no trace of this suture of the basi-cranial axis. Further there is no trace on the radiogram (Fig. 1) of the line of fusion. The faint parallel lines visible on the outer surface of the left half of the skull normal to the ventral surface extend but a portion of the way across the section, and correspond to the bony walls of a venous channel. This vascular channel with its surrounding bony condensation lies in the centre of the ventral aspect of the basi-occiput and is too near the anterior margin of the foramen magnum to be related to the sphenoidal suture. Thus the absence of the cartilaginous suture and the absence of the dense line of bony union at the suture suggest that the skull is at least more than 25 years of age.

2. *The Sagittal Suture*.—The sagittal suture is closed both ectocranially and endocranially except over a distance of

1 cm. at a short distance behind the bregma. The lapsed union of this small portion, in relation to the underlying motor and secondary sensory areas, is a common feature of any collection of skulls, and should be discounted in assessing age. The absence of any closure in the other sutures of the cranial vault suggests that the skull is definitely less than 38 years. The complete closure of the sagittal suture as a whole indicates that the age of the skull is over 25, and possibly over 30.

III. Radiographic Examination

1. *Venous Sinuses of the Diploë*.—The radiograms of the two halves of the sectioned skull show a high state of development of the venous sinuses of the diploë. These venous sinuses usually reach their maximum development in the fifth decade. This skull, therefore, would appear to belong to a man in the fourth decade. It is extremely rare to see such development of the venous sinuses of the diploë under 30 years of age.

2. *The Meningeal Grooves*.—The grooves due to the meningeal vessels on the inner aspect of the cranium offer no abnormal feature. There is no evidence of pathological bone formation in relation thereto.

IV. The 'Lesions' of the Vault

Both naked eye and radiographic examination fail to indicate any evidence of that tissue reaction which is invariably registered by areas of rarefaction in relation to areas of hyperostosis. The 'lesions' are limited entirely to the outside of the skull, and especially to the right half. They are produced by an artefact such as a blunt burr or bradawl. The fact that the diameter increases with the depth, the absence of changes in the margin, and the relative uniformity of the lesions suggest the handiwork of man. Here and there several such lesions have been run into one another so as to simulate a serpiginous lesion. A lesion in the right mastoid process displays the non-pathological features clearly.

The radiograms illustrate the sites of the bony lesions. There are visible on the radiogram a few dense shadows. These correspond to flecks of white paint on the outer surface of the skull, the ones near the postero-inferior angle of the left parietal and on the right frontal bone are very well marked (Fig. 2).

FIG. 2.—Radiogram of the right half of the skull showing the areas of erosion devoid of surrounding areas of hyperostosis. The venous sinuses of the diploë and the meningeal veins are well shown.

V. Microscopic Examination

The three slides show

- (1) Scrapings of the white paint from the outer surface of the skull. These flecks are visible on the radiogram (Fig. 2).
- (2) Debris consisting of dust and varnish (shellac) from one of the depressed lesions.
- (3) The negative result of repeated testing for haematin crystals.

VI. The Staining of the Skull

The outer aspect of the skull has been coated with shellac varnish. The inner aspect is deeply stained on the left side with old blood clots, which may have been the result of the normal *post mortem* changes apart from injury to the skull or

brain. The relative absence of staining within the right half suggests that the body lay after death on the left side.

The lesions occur mainly on the right side of the skull, and it was at first thought that molten metal (such as that from a lead coffin) might have produced the 'lesions'. No trace of a heavy metal could be found therein radiographically or chemically, and no trace of charred bone could be found.

Conclusion

The skull is that of a well developed but atypically low browed male of at least 25 to 30 years, displaying no pathological lesion. In particular there is not the slightest evidence of syphilis.

B THE FEMUR

1 Gross Appearance

The right femur is that of a well developed male of a stature of at least six feet. The muscular and ligamentous markings are not salient and do not suggest association with a highly developed muscular system. There has been *post mortem* destruction (probably mechanical) of the upper portion of the neck near the head, and, to a lesser degree, of the anterior aspect of the great trochanter. The anterior aspect of the shaft displays some amount of erosion. There is no naked eye evidence of the lines of epiphyseal fusion.

II Radiographic Examination

The radiograms of the proximal and distal extremities of the femur show but little trace of the line of fusion of the upper epiphysis, and no trace of the line of fusion of the lower epiphysis. Thus the femur is that of a man of an age considerably over 21 and probably over 25 years of age. The absence of the line of fusion of the distal epiphysis suggests that the man must have led an active life for many years after reaching adolescence, as such lines tend to persist more markedly in those of a relatively sedentary habit. The circular area of increased density in relation to the medial border of the external condyle of the femur is the dense plaque of bone at the insertion of the anterior cruciate ligament.

III Pathological Examination

There is no trace on the bone or on the radiogram of any abnormal periosteal or endosteal inflammatory reaction. The femur has been heavily varnished with a shellac varnish, and a portion of the scale removed was seen to consist of shellac only. There is no evidence of a syphilitic periostitis.

Conclusion

No syphilis. No Lord Darnley.

Australia.

[FROM OUR OWN CORRESPONDENTS.]

University of Sydney

PROFESSOR F. P. SANDES and Dr. AENEAS MACDONNELL have been nominated by the Senate to represent the University of Sydney at the first annual meeting of the College of Surgeons of Australasia, to be held at Canberra from March 31st to April 2nd next year. The Council of Advice to the Pastures Protection Board of New South Wales has intimated that approximately £2,500 per annum has been promised for a period of five years by various pastures protection boards for the purpose of assisting the University Veterinary Science School and the Glenfield Research Station with funds to enable research work to be undertaken as an extension to present activities. The council asked for advice how the amounts subscribed could be best expended. The late Professor Liversidge has bequeathed to the University a sum of £2,000 to form a scholarship fund for proficiency in chemistry, and a sum of £500 to found a research lecture-ship in chemistry.

Hospital Maintenance

Figures furnished by the New South Wales Ministry for Public Health show that during the eleven months to the end of last November £531,696 had been spent in hospital maintenance, including subsidy, special grants, and the liquidation of overdrafts. Of this, the Sydney Hospital received £104,629, the Royal Prince Alfred Hospital £64,749, and the Royal North Shore Hospital £36,293. Since January 1st additions and alterations to hospitals throughout the State had been carried out at a cost of £74,448. Other items of expendi-

turo during the same period included the cost of ambulance services, £30,207, subsidizing of doctors in bush settlements, £3,982, bush nursing centres, £2,500, and institutions for the deaf, dumb, and blind, £3,050. In the relief of distress £80,282 was expended during the same period by the Chief Secretary's Department.

A Plea for Self-supporting Hospitals.

Professor R. J. A. Berry, dean of the Faculty of Medicine in the University of Melbourne, recently gave an address at Wesley Church on "Hospitals, voluntary or self-supporting?" He pointed out that the world's practice to-day was to concentrate all medical effort—hospitals, laboratories, and pre-clinical sciences—at the one spot, and to endeavour to bring all medical knowledge to bear on the study, treatment, and prevention of disease. This had resulted in the creation of self-supporting hospitals in place of those of the voluntary type. Professor Berry then explained his scheme for the creation of a great medical centre for Melbourne, an account of which was given in the *Journal* of April 21st (p. 680). Proceeding he said that Great Britain was the home of the voluntary hospital, which was originally a noble charity, and which, up to the beginning of the present century, had fully met the needs of the times, and compared favourably with the hospital system of any other country. To-day, he thought, expert English opinion was against the system, because it had not developed in proportion to the needs of the community, and, further, it had failed to meet the growing needs of the middle classes, to maintain an adequate standard in regard to sites and buildings, and to co-ordinate its services in the interests of the community. Voluntary hospitals were, he alleged, demanding payment from their patients for board, lodging, and food, while for financial reasons they admitted many persons other than the indigent sick. Free medical service by the profession, however, was still retained in its original integrity. Of recent years there had been two main factors at work tending to destroy the voluntary principle: first, the rapid progress of medicine, which had compelled all hospitals to extend their medical activities and equipment; and secondly, the great war, which had impoverished the peoples of Great and Greater Britain. As a result the cost of upkeep per bed in the London voluntary hospitals had increased by 100 per cent, and repeated appeals for financial assistance had to be made to the most heavily taxed people in the world. Many patients, who formerly not only sought private medical advice, but also contributed their offerings to the voluntary hospital, were now seeking free hospital medical treatment—partly from economic reasons, partly because they thought that the well-equipped hospital gave better service than the private nursing home, and partly because the morale of modern democracy was being undermined by bonuses from the State. Professor Berry thought, therefore, that the voluntary hospitals—unless they could revolutionize their finances—were doomed. Although he had been educated under the British voluntary system, it had been impossible for him to pass, as he had done in 1927, from an examination of the voluntary system of Britain to the self-supporting hospitals of America without being profoundly impressed with the latter. These hospitals were not only open to all classes of the community, but were in association with the university. In addition, the medical staffs were well paid for their services, and a contented staff meant an efficient service. In the Canadian and American self-supporting hospitals the sources of revenue were (1) receipts from endowments, (2) payment for medical and other hospital services from wealthy and middle-class patients, (3) payments from province, State, city, or municipality for the actual cost of board, lodging, and medical treatment accorded to those unable to pay themselves. Under this system the hospitals were not in debt, and the members of the medical profession and others working in them received payment for services rendered. There was no pauperization of the people, and no exploitation of the medical or of any other profession. Professor Berry, therefore, was of the opinion that to enlarge and extend the existing hospitals of the voluntary type on their present inadequate sites would be to perpetuate a system which was gravely open to question and contrary to the world's accumulated medical and practical experience.

New Chair of Obstetrics

A letter received by the council of the University of Melbourne from the Premier's office announced the intention of the Government to co-operate with the University in the establishment of a chair of obstetrics, and asked for the submission of a scheme to carry out the decision. The council referred the letter to the faculty, and accepted the recommendation of the latter that the appointment should carry a salary of £1,500 per annum, with the right of private consulting practice. The recommendation of the faculty that the appointment should be a five-yearly one was referred back to that body for further consideration.

Proposed Clinical Hospital at Melbourne

The establishment of a clinical and research hospital in connexion with the University of Melbourne is still under consideration. The council of the university has given its approval to the scheme, and the faculty of medicine has appointed a committee to consider the method of administration and other problems connected with the proposed hospital.

Post-graduate Refresher Course

The annual refresher course arranged by the Melbourne Permanent Committee for post-graduate work was held in Melbourne from August 6th to 17th. This course ran concurrently with a special course of lectures delivered by Professor F. R. Fraser, of St Bartholomew's Hospital Medical College, London, who has been visiting Melbourne at the invitation of the Post-graduate Committee.

Scotland.

Scottish Quarterly Statistics

SALIENT features of the vital statistics for Scotland during the second quarter of the year 1928 include a birth rate of 21.2 per thousand, a marriage rate of 6.5 per thousand, and a death rate of 13.6 per thousand. In the larger burghs, taken individually, the death rate ranged from 17.2 in Perth, 15.4 in Aberdeen, 15.3 in Dundee, and 15.2 in Greenock, to 11.2 in Clydebank, 11.6 in Falkirk, 11.7 in Dunfermline, and 11.9 in Motherwell and Wishaw. In Glasgow the quarterly death rate was 14.6, and in Edinburgh 14.2. Deaths of children less than 1 year old numbered 2,112, equal to an infantile mortality rate of 62 per thousand registered births. In the larger burghs, taken individually, the infantile mortality rate varied from 119 per thousand births in Aberdeen and in Greenock, and 114 in Ayr, to 52 in Dunfermline, 55 in Clydebank, 71 in Motherwell and Wishaw, and 76 in Kilmarnock. In Dundee this rate was 99, in Glasgow 89, and in Edinburgh 83.

Montrose Royal Asylum

The report of the Royal Asylum of Montrose for the year ending May 15th, 1928, by Dr C. H. Shaw, physician-superintendent, shows that the number of patients under treatment in the asylum during the year was 371, of these 73 were discharged—56 left recovered, 8 relieved, 9 not improved—while 62 died. The total number of certified patients admitted was 148, including 70 men and 78 women, of whom 46 were private patients. During the year 27 voluntary patients were admitted, thus doubling the number of persons in this category undergoing treatment. Of the admissions, 24 had suffered from at least one previous attack. It is noted that in 3 cases the recurrence was due to the renewed abuse of alcohol, while in several other cases home conditions were not satisfactory. Dr Shaw suggests that a local after-care association, whose members would take an interest in discharged patients and arrange for suitable employment, would be a great benefit. It is also noticed that the standard of physical health among the persons admitted was low, 25 of them were in a very feeble and exhausted condition, while 70 were described as weak. With regard to the causes of mental breakdown, heredity was ascertained to be a factor in about 40 per cent of cases, while in 8 per cent alcoholic intemperance was assigned as a cause. The latter figure

is somewhat higher than in recent years, although there has been a great diminution in the frequency of alcoholic excess as a cause. Adverse economic conditions were found to be a causal condition in 13 cases, in which illness was due either to lack of proper nourishment or to unemployment. With regard to the deaths, the average age at death was 60 years, and evidence of the weak physical condition of many of the patients received is shown by the fact that 7 died within a week of admission and 15 within one month. It is pointed out that this asylum was originally erected by voluntary subscription in 1781 as a charitable institution, being the oldest foundation of its kind in Scotland, and that it still preserves this character. At present 38 patients benefit by a special rate—less than that charged for parish patients—because of their necessitous circumstances. During the year 5 male and 13 female nurses passed the preliminary and 5 nurses passed the final examination of the Royal Medical-Psychological Association.

Sir Arthur Keith, Hon. F.R.F.P.S.

At a meeting of the Royal Faculty of Physicians and Surgeons of Glasgow, held on September 3rd, the honorary Fellowship was conferred upon Sir Arthur Keith, M.D., F.R.S. During the course of an "At home," given in the Faculty Hall to members of the British Association for the Advancement of Science, Sir Arthur Keith signed the roll of honorary Fellows. It will be recalled that last year Sir Arthur Keith was President of the British Association, and his address on "Darwin's theory of man's descent as it stands to-day" was published in the *British Medical Journal* on September 10th, 1927 (p. 439).

Edinburgh Prison Medical Officer

The Secretary of State for Scotland has appointed Dr. Allen Thomson Sloan to be medical officer of the Prison of Edinburgh. Dr. Sloan is a former Edinburgh Academical football player and on many occasions played for Scotland in international matches, commencing in 1914. Dr. Sloan graduated M.B., Ch.B. at Edinburgh in 1921.

Ireland.

Tuberculosis in Belfast

In his annual report for the year ending December 31st, 1927, Dr. Andrew Trimble, chief tuberculosis officer of the county borough of Belfast, submits certain practical suggestions for the further development of the work of the tuberculosis department, which has been in operation for fourteen years. He advocates more intensive education of the people in public and personal health and in the prevention and cure of tuberculosis, he thinks it reasonable also that there should be preventive inoculation against this disease, beginning with every infant born into a tuberculous family. More open-air schools are said to be required, it is stated that this subject is to be dealt with shortly in a joint report by Dr. Trimble and the chief school medical officer. Another suggestion made is that there should be added to the medical curriculum a course in the history, prevention, diagnosis, and methods of treatment of tuberculosis in the individual, and the means of dealing with it in the community. The accommodation for children suffering from non-pulmonary forms of tuberculosis is said to need extension. Dr. Trimble favours the extension of medical benefits to insured persons in Northern Ireland on the same terms and conditions as at present prevail in Great Britain, with, possibly, the inclusion of dependants. He adds that some reinforcement of his staff will be needed if the newer and more delicate methods for the diagnosis and control of tuberculosis are to be applied effectively. During the year under review 2,086 persons were notified, as compared with 1904 in the previous year, of these 51.7 per cent were found to be infected, 5.3 doubtfully so, and 43 per cent were free from the disease. In 27 per cent of the definitely infected cases there was clear indication of the possibility of direct infection by living in contact with tuberculous patients, Dr. Trimble draws attention to the continuance of overcrowding, despite the efforts made by

the Belfast Corporation to provide new residential accommodation with a low weekly rate of "purchase repayment," but hopes that the difficulty will eventually be overcome. During 1927 the Belfast Insurance Committee gave £150 for the provision of an artificial light installation at the Central Tuberculosis Institute, and shortly afterwards a mercury vapour lamp was presented to another tuberculosis institute in the city. The open air school has also been enlarged, but the demand for admission is far in excess of the accommodation. It is stated that the Government of Northern Ireland has issued only one form of licence for selling milk—namely, Grade A (T.T.) milk—and the Tuberculosis Committee has resolved to purchase this only in future for the municipal sanatorium and the hospital for tuberculous children. The hope is expressed that the time is not far distant when no other grade of milk will be allowed to be sold.

Preservatives in Food

The Minister for Local Government and Public Health in the Irish Free State has issued an order prohibiting the use of certain preservatives in foodstuffs on and from October 1st, 1928. It is made illegal to sell, import, or produce food which contains specified preservatives or other improper ingredients, and power is given to local authorities and to the Customs officials to deal with breaches of what are named as the Public Health (Preservatives, etc., in Food) Regulations. The Secretary to the Ministry, in a circular letter to local sanitary authorities dealing with the aim and scope of the regulations, points out that they follow the lines of similar ones made in the neighbouring countries in conformity with the recommendations of a committee of experts. They provide for the prohibition of the importation and sale of articles of food to which preservatives and other specified substances have been added, a preservative is defined as any substance which is capable of inhibiting retarding, or arresting the process of fermentation, acidification, or other decomposition of food, or of masking any of the evidences of such process, or of neutralizing the acid generated by any such process. It does not include common salt, salt-petre, sugars, lactic acid, acetic acid or vinegar, glycerin, alcohol or potable spirits, spices, essential oils, or any substance added to food by the process of curing known as smoking. No person may manufacture for sale or sell any article of food which contains any of the following preservatives: compounds of antimony, arsenic, cadmium, chromium, copper, mercury, lead, zinc, the vegetable colouring matter gamboge, and the coal tar colours—namely, picric acid, Victoria yellow, Manchester yellow, aurantia, and aurine. The use of sulphur dioxide or benzoic acid is permitted in very minute quantities in connexion with the manufacture of certain named commodities. No person may sell any article for use as a preservative, or any colouring matter for any article of food if such use would be contrary to the regulations. No cream may be sold which contains any thickening substance. Strict regulations are provided to ensure that all articles shall be properly labelled and described. The regulations make very full provision for their enforcement by the sanitary authorities.

Typhus Fever in Connemara

What was at first feared would develop into one of the recurrent severe outbreaks of fever which in former years caused serious havoc in the poorer districts along the sea-coast of Connemara occurred last week in Bealadangan district, one of the poorest areas in South Connemara. The infection has, however, it is thought, been brought under control, and so far there have not been any further additions to the ten cases of typhus which have been brought to the Galway Central Hospital. The outbreak is confined to two houses in the village of Drinn, in one instance nine members of one family have been stricken down and are in the hospital the other case is that of an old man who lived next door to the stricken family. The mother of the family of whom nine are in hospital died about fourteen days ago, and it is believed, but not definitely known, that her death was due to typhus. The father of this family and one of the children are in a serious condition.

Correspondence.

IRELAND AND THE QUEEN'S INSTITUTE OF DISTRICT NURSING

SIR,—With keen disappointment and a feeling akin to despair I have read the paragraph headed "Queen's Institute of District Nursing" which appears on page 464 of the *British Medical Journal* of September 8th.

Associated most closely as I have been with the work of district nursing of the sick poor in their own homes throughout the whole of Ireland since the year 1889, I am in a position to state with emphasis that this beneficent and most valuable patriotic work has been successfully carried on throughout the length and breadth of Ireland by a noble band of highly trained women.

The Queen Victoria's Institute for Nurses was constituted under Royal Charter dated September 20th, 1889, and supplemental Charters dated respectively March 31st, 1898, and September 5th, 1904. Recently the title of the Institute has been changed at the instance of His Gracious Majesty the King to "The Queen's Institute of District Nursing."

The aims and objects of the Irish Branch are

(a) To stimulate interest in district nursing and to ensure throughout Ireland the most skilled home nursing service without distinction of creed and with these objects in view (1) to provide for nurses special post-graduate courses in district work midwifery infant welfare school and tuberculosis visiting so as to qualify them for district nursing as well as for all branches of public health work (2) to supply nurses to local district nursing associations (3) to arrange for the inspection of the work of each nurse twice yearly and of the homes once a year, or more often as is considered advisable.

(b) To encourage the formation of a central or county nursing association in every county in Ireland for the purpose of combining the existing nursing associations and to promote the development of new district associations where required.

The business of the Irish Branch is vested in an executive committee composed of representatives from both Northern and Southern Ireland in proportion to the relative population of those districts.

The supplemental rules for Northern Ireland provide that—

1 There shall be an advisory committee for Northern Ireland consisting of not more than forty members elected annually by the county committee representing each of the six counties and two county boroughs of Northern Ireland.

2 The duties of the said advisory committee shall be

To promote and co-ordinate the work of the Irish Branch in Northern Ireland and as far as may be thought desirable to assist district nursing activities in general there.

To inform and advise the executive committee of the Irish Branch with regard to matters affecting the Irish Branch in Northern Ireland.

To report to the said executive committee as soon as may be after each meeting of the said advisory committee all proceedings at that meeting.

To nominate to the said executive committee not more than six suitable persons to act as representatives on the said executive committee.

To elect at its first meeting three trustees, who shall be jointly responsible for all capital sums raised in Northern Ireland in connexion with the said Institute, and for the payment of all interest accruing on such sums to the finance committee of the Irish Branch, and thereafter to fill any vacancies which may occur amongst the said trustees.

To receive a report from the aforesaid trustees at each annual meeting of the said advisory committee.

Such has been the existing constitution of the Irish Branch up to the present. For wellnigh forty years the work of the Queen's Institute has been carried on throughout Ireland without any question of either political or religious bias having arisen. In Dublin there are two homes for those already fully trained and registered nurses who are candidates under the Queen's Institute for the statutory period laid down for their training in district nursing before they can become Queen's nurses. Those homes it is true, are respectively Protestant and Roman Catholic. But outside their doors the Queen's nurses are just all that this honourable title implies, and nothing more.

It pains me to think that it should be left to my fellow countrymen in Northern Ireland to harbour the suspicion

and in veiled terms to suggest, that political or religious differences can possibly arise in connexion with the sacred work of nursing the sick poor of Ireland. That this suggestion has been made is clear from a report (which I enclose) of a subcommittee appointed by the Central Council of the Queen's Institute in London to consider the situation which has arisen in Ireland. That report was adopted by the Council on July 11th of this year.

It is lamentable that, whereas a project which would have interfered with the unity of Ireland in regard to the profession and practice of medicine was happily averted a few years ago by conciliatory and statesmanlike measures influential people in Northern Ireland and its capital should now attempt to subject the nursing of the sick poor of Ireland to an experiment which might prove disastrous, and which is quite uncalculated for.

The opinion of the medical profession is, I venture to think, well and correctly expressed in a resolution which was adopted by the Royal College of Physicians of Ireland on June 1st, 1928. It runs as follows:

"Resolved. That the President and Fellows of the Royal College of Physicians of Ireland have learned with regret that a proposal has been made to the Central Council of Queen Victoria's Jubilee Institute for Nurses to establish a branch of the Institute in Belfast separate and distinct from the All-Ireland Branch which has through so many years successfully and harmoniously carried on its work in all parts of this country.

The President and Fellows hope that the Central Council will not disturb the present constitution of the Institute in Ireland under which valuable service has been rendered to the country in the field of public health and private nursing of the poor.

The paragraph in the current *Journal* concludes with the following extraordinary, if not in fact dishonest, sentence: "The duties of this All-Ireland Council will, it is stated, be purely formal, but the principle of unity in nursing, even if only in name, has been insisted on by the headquarters of the institute" (Italics mine).—I am, etc,

Dublin Sept 10th

JOHN W. MOORE, M.D.

* * We willingly publish Sir John Moore's account of this regrettable dispute. He recognizes, of course, that the statement he impugns was merely quoted by our Dublin correspondent.—Ed., B.M.J.

TONSILLECTOMY AND REMOVAL OF ADENOIDS

SIR,—The article by Mr Sandiford and Dr Clayton in your issue of July 28th (p. 149), and the subsequent correspondence dealing with the guillotine and ethyl chloride, have brought out many points of interest. There are, however, several aspects of the question which have not been touched, and which I think are of considerable importance.

My own investigations have convinced me that lymphoid tissue, in the nasopharynx and the tonsils, enlarges and carries the name of "adenoids and tonsils" as a result of sepsis. If this is so, it clearly precludes absolutely such rapid methods as are advocated, for they allow no time for searching in the nose for signs of sepsis, or for dealing with such sites if they are present, which, in my experience, is the case in rather more than 20 per cent of patients in this class. To leave the sepsis which has caused the adenoids is to remove the sign and not the cause, and to condemn the child to carry in his years of growth and education a focus of infection which, if it is not cured spontaneously, affects the natural bodily growth and the development of the intellect.

The second aspect of the matter, which is undoubtedly important, is the amount of haemorrhage which follows operation. When rapid procedures are employed there is not time to utilize the modern methods which limit haemorrhage to half an ounce or so, and quantities of blood are often shed which are far greater than a child should lose.

A further aspect of the matter is the question of the pain which follows operation with the guillotine. This, to my mind, is far greater than that experienced after the gentler methods of dissection. To these objections to the rapid methods advocated by the authors I would add the psychological factors which must operate in children who

are so rapidly anaesthetized that there can be no time to gain their confidence. I would submit that the operation for the removal of adenoids and tonsils is one in which all efforts should be made by the surgeon to assure himself that he has dealt with every condition in the nose likely to need surgical attention in the future, and that the loss of blood in these operations should be considered as being as serious in its effects as in operations in other situations.—I am, etc,

London S.W. Sept 4th

A. LOWNDES YATES

SIR,—It was with considerable interest that I read Sir Charters J. Symonds's letter on the use of ether in tonsillectomy, published in the *Journal* of September 8th (p. 465), as I have been waiting for someone more able than myself to reply to those who advocate chloroform.

I have acted as locum tenens in general practices in many parts of the country, and the number of general practitioners who give chloroform for such operations as tonsillectomy, extraction of teeth, circumcision, etc., has surprised me. When one suggests ether—which I always give, and refuse absolutely to give chloroform for such cases—one is regarded almost suspiciously as being incompetent. This view is, I believe, in the North of England at any rate, due to the large number of Scottish graduates who have never learned the technique of other administration.

I hope that Sir C. J. Symonds will find time to describe the type of Clover's apparatus which he uses. The one I employ has no special features other than its wide bore, but I find any sort of apparatus with a bag rather terrifying to small children, and for them I use open ether. The period of induction by this method is very little, if any, longer than by the closed method.—I am, etc,

WRIGHT LAMBERT

Cornholme nr Todmorden, Yorks Sept 10th

THE IMMEDIATE DIAGNOSIS OF PULMONARY ASBESTOSIS AT NECROPSY

SIR,—Having recently had occasion to examine the fresh organs from a case of suspected pulmonary asbestosis it occurred to me that by making direct smears from the cut surface of the lung it should be possible to detect immediately the presence or absence of the characteristic "brown bodies" of this disease. The result was extraordinarily successful. A drop of the "lung juice," obtained by squeezing a small piece of the fibrosed lung tissue on a slide and covering with a coverglass, showed myriads of these remarkable bodies, and enabled a diagnosis to be made forthwith. Subsequent histological examination of the lungs showed their presence in large numbers, especially in the catarrhal alveoli bordering on the areas of fibrosis, and in smaller numbers within the fibrotic patches themselves.

So far as I am aware these bodies, admirably figured and described by Cooke, Stuart McDonald, and Simson, do not occur except in the lungs of asbestos workers. They have been present in large numbers in three cases of asbestosis examined after death by my colleague Dr A. L. Taylor, and in a considerable experience of lung histology in all sorts of diseases I have never previously encountered them. In the present instance, the patient, a woman aged 34, had been employed in an asbestos works for sixteen years, chiefly in the manufacture of asbestos mattresses. She had been away from work two years before her death. Both lungs were extensively fibrosed and very anthracotic, but there was no evidence of tubercle, syphilis, or silicosis.

It may be mentioned that dried films, suitable for the demonstration of the Prussian blue reaction given by these bodies, as well as for their more detailed study, were equally successful. In passing, one may express the conviction that these bodies are actual derivatives of the inhaled asbestos, and emphatically not animal or vegetable forms.—I am, etc,

THE ALLEGED HIGH FERTILITY OF JEWS

SIR,—I was greatly interested in the letter of Dr M Sourasky in your issue of September 8th (p 469), and I cannot regret my statement at Cardiff, since it has given rise to such a valuable communication. It is true that I was referring only to orthodox Jews living in obedience to the Mosaic law, and I was quite aware that modern conditions had affected this race as well as their Gentile neighbours. It hardly seems possible, however, to explain wholly the remarkable figures quoted, by a "disregard of Biblical injunctions" on the part of the Jews. Is it to be supposed that the Jews in Prague, Bohemia, and Bavaria were, in 1900, restricting their families to double the extent that the Christians of those districts were doing? Surely some other factor, biological or psychological, must have been at work. Reliable figures or facts on the decrease of the birth rate are so difficult to obtain (as we found at Cardiff) that I suggest a closer examination of the records from Jewish sources would be of the greatest scientific value. One thing certainly seems to emerge, and that is that a fall in the birth rate follows rather than precedes an increase in prosperity. The higher the standard of education among Jews, the higher their standard of living and their material prosperity: the lower is the average birth rate, and thus, I am informed by a competent Jewish observer, is generally true, whether they maintain the rule of the Mosaic law against deliberate restriction or not—I am, etc.,

London WC Sept 10th

LETITIA FAIRFIELD

SPIRIT AND BIPP TREATMENT

SIR,—In your issue of May 26th (p 892), Mr N L Maxwell Reader describes a case of compound fracture treated after the method of Professor Rutherford Morison Bipp is the reagent used, that is a detail. It is only fair to the memory of the late Lord Lister to claim for him a decided priority as to the method. Although his name never will be forgotten, it is the fear that his technique is not familiar to the gentlemen named that prompts me to ask you to republish the salient features of what are almost parallel cases.

MAXWELL READER (1928)

On December 7th 1927 a feeble old lady of 77 was knocked down by a motor lorry and sustained a severe compound comminuted fracture of the lower end of the right tibia and fibula. The wound was now freely swabbed out with methylated spirit after which it was carefully dried. A small quantity of hipp was introduced into the cavity and thoroughly rubbed into every available nook and cranny. The dressing consisted of long pads of gauze freely soaked in spirit each pad being liberally sprinkled with boric powder. The pads were laid along the wound and did not encircle the limb. The plasters were applied as follows. The old lady remained very feeble and debilitated but no special pain was felt in the foot, and the temperature caused no alarm. On the seventh day—more from curiosity than necessity—I removed the dressing. The wound was quite dry. From start to finish not a bead of pus or even serous oozing occurred. At the end of the month the splint was removed daily for massage and a fortnight later discarded altogether.

JOSEPH LISTER (1867)

"Case 10—Thomas McB, a labourer who gave his age as 52 but had the appearance of a much older person was admitted having been knocked down by a lug gage waggon producing a compound fracture in the lower third of the limb. On diluted carbolic acid was applied freely to the interior of the wound by means of lint held in a pair of dressing forceps and a crust was formed of blood mingled with the acid covered with lint over which a cap of tin was placed. The limb was put up with lateral wooden splints.

"Next day the surface of the crust was touched with carbolic acid and the same treatment was continued for the following fortnight during which the limb was entirely free from pain redness or suppuration. I was present when the crust was removed eighteen days after the accident. Not a drop of pus existed beneath it. Six weeks and three days after the receipt of the injury the splints were removed the bones being satisfactorily united. This is an excellent example of the effects of the carbolic acid treatment in a compound fracture of the leg of average severity. No simple fracture could have caused less disturbance either local or constitutional.

Here we have two excellent examples of the antiseptic method of dressing wounds, separated in time by almost

exactly sixty-one years, both surgeons claiming originality in the method adopted. By priority, I opine that Lister wins. He used crude carbolic acid—that's a detail—I am, etc.,

A C F HILFORD, MD

THE FORGOTTEN SWAB

SIR,—The detailed account of the end-results of the two forgotten swabs in the abdominal cavity given by Dr H Roland Segar in your issue of January 21st (p 95) has greatly interested me, and I feel that Dr Segar will be equally interested to hear the end-results of a third forgotten swab.

Early in 1926 I came across a patient, who was referred to me by a physician, with a provisional diagnosis of tuberculous peritonitis. She had a sinus in the abdominal wall, following an abdominal operation for some pelvic trouble some six months before. A distinct lump could be felt in the abdomen about the level of the umbilicus. On opening the abdomen I found a sponge walled off by coils of intestine and omentum. The sac was full of pus, and the sponge measured 12 in by 12 in, with a tape at one of its corners. It had eroded the walls of the intestines. The faecal stains on the sponge were suggestive of perforation. On removal of the sponge the patient had faecal fistulae, which healed spontaneously in ten days, and then recovery was uneventful.

From that day I have had a small smooth silver letter "S" stitched to every sponge, at one of its corners, in my theatres, and every patient is x-rayed or screened before discharge, and I have had no more worries about sponges—I am, etc.,

PAYING PATIENTS IN VOLUNTARY HOSPITALS

SIR,—A year ago (October 22nd, p 751) you drew attention to the dangers of the numerous voluntary contributory schemes which were springing up all over the country, and which, under the guise of "insurance" or "helping the hospital," secured for their clientele, who demand their money's worth, services at far below cost price. During the past six months the medical profession has been much concerned regarding the National Health Insurance Act 1928, under which approved societies will be able voluntarily to enter into a "commercial arrangement" on behalf of their members for every benefit that a "charitable institution," which includes a voluntary hospital, can provide, but here again at less than cost price. In 1926 only 10 per cent of the cost was paid.

The poor old ship—the voluntary hospital—staggers under these friendly blows, meant to help her and to keep her afloat. And now, in the *Journal* of August 18th (p 317), you refer in some detail to a third attack the report of the Pay Beds Committee of the King Edward's Fund for London, and quite correctly say that "changes in conditions in the metropolis will certainly have their reactions upon the country generally." One calls it an "attack" because these facilities for the middle and upper classes are not to be paid for by them in full. The capital cost of provision of buildings and equipment is to be found by "special appeals." This report should be read carefully by all interested in the transition period in hospital accommodation.

But, before criticizing the report, may I draw attention to two seeming errors in your article. You state that it would appear that the Committee inclines to the solution presented by the British Medical Association policy that, where the pay beds are an integral part of the hospital building, a "closed" staff is generally necessary. Now the policy of the Association is only concerned with two groups of private patients—namely, those in the public wards and those in a nursing home attached to the hospital. No policy has been adopted so far with regard to private patients in private wards and private rooms inside the hospital building. The deputation from the Association overlooked this fact, and stated that the Association was in favour of the visiting staff (that is, a

"closed" staff) attending such patients. This statement is incorrect, and I very much doubt whether it will be accepted by the profession generally. It would be intolerable in the case of wealthy patients using such accommodation—just because, for instance, there is no alternative accommodation available in a nursing home, attached or unattached to the hospital—who desire to, and who can well afford to, pay the fees of their own general practitioner and his recommended consultant or specialist, that they should be forced to accept a member of the visiting staff, their own preferences being shown in the door.

Then, again, you state that the Committee, in its recommendation that no fees should be charged in the public wards by the medical attendant unless and until the full maintenance charge is paid, shows "a sharp difference of opinion" from the Association policy, and you quote in support of this contention a certain section of the policy, but that section contains a statement—wholly you omit—that it should not be quoted as referring to private patients. The Association policy should be interpreted that the payment "in full" for maintenance and any payment of the medical attendant form a well balanced situation, and that unless and until the former condition is fulfilled the latter cannot arise. The charging of less than full maintenance cost is a means by which the patient can be saved medical fees. This is being done now.

In considering the Pay Beds Committee's report it at once becomes apparent that its value has been reduced because there was not on the Committee a single medical practitioner representative of the private consultant or private specialist not attached to a voluntary hospital, nor of the thousands of general practitioners practising in London, that not one witness from these three groups was called to give evidence, and that the Council of the Association did not put forward to give evidence any one representative of these groups. Had that been done we should not have had a report which brushes aside so readily, and without any argument, the suggestion that the provision of the 4,000 beds said to be necessary for paying patients could be made gradually by means of, say, 500 beds—in private hospitals placed in the suburbs around London—in favour of providing them at the voluntary hospitals. In the former case the general practitioner could continue, if he so desired, to attend his patients to his scientific and financial advantage. In the latter case the visiting staffs evidently will keep for themselves, and for a few others they select, all patients sent in, to the exclusion of the rest of the medical profession. It is over this problem that the medical profession will become divided, and the unity in the Association be likely to be jeopardized.

The anxiety of these three groups in the profession will not be lessened when they read that the chairman of the Hospital Committee of the Association, representing the Royal College of Surgeons, expressed these opinions:

- (a) The likely clientele of these pay beds would be 2 per cent of a population of two and a half million persons (1134-1135).
- (b) The payment (for hospital treatment) should be through some voluntary and general insurance (1136).
- (c) The paying block would finally be under the control and direction of the lay authorities of the voluntary hospital in precisely the same manner as the rest of the clinical side (1109).
- (d) The provision of accommodation attached to voluntary hospitals for the well-to-do would be approved by the profession (1050).
- (e) If a block containing beds for paying patients is attached to a voluntary hospital it ought to be for those patients who are consigned to the members of the visiting staff. Each voluntary hospital should employ its own staff (1128).
- (f) The treatment of private patients by any one other than the visiting staff of the voluntary hospital providing this accommodation would not be entertained (1101).
- (g) The private practitioner should come in for consultative work or be present at an operation and see the patient several times afterwards with the member of the visiting staff concerned but he should not be responsible for the treatment (1121).

It would be asking too much to be allowed a full criticism of the report, but the profession should ponder over the following statements of the Committee:

- (1) The voluntary hospital system is becoming largely a co-operative effort.
- (2) It is impossible to obtain full hospital facilities for well-to-do patients except at a voluntary hospital.

(3) The general wards of voluntary hospitals should now be thrown open to those of moderate means on the same terms and conditions as apply to the sick poor, no payment for medical treatment being allowed. The wealthy should be catered for in pay rooms, private wards, and attached nursing homes.

(4) The means by which general practitioners would be kept in contact with their patients in private wards and pay rooms would be (a) by being allowed access to their patients at all reasonable times, (b) being communicated with when anything is going to be done—an operation to be performed, (c) being informed of the patients' exact condition on discharge, and (d) may get advice as to what should be done. (Such an arrangement the Association's representatives stated would entirely satisfy the Association (1205-1208).)

(5) The committee of management of the hospital should lay down certain rules or limitations as to the medical practitioners who were allowed to come into the attached nursing home.

(6) "King Edward's Fund should prepare and publish year by year, for the information of the public, a list of pay beds, wards and rooms at the voluntary hospitals with rates of charges and other particulars as the existence is not generally known." (As it is contemplated that the visiting staffs alone would attend these patients—being paid fees for their services—they would find themselves, were this proposal adopted, involved in a novel form of touting for practice amongst the middle and upper classes.)

(7) The well-to-do pay bed patients would assist the hospitals to finance their ordinary work. (Hospital administrators are always optimists.)

The voluntary hospitals of the country—originally built, equipped, maintained, and partially endowed for the sick poor—are now being appropriated, in great part with general consent, by members of every rank in society for their own use under contributory schemes for the industrial and lower middle class, by approved societies' schemes under the National Insurance Act, 1928, and now, as recommended under schemes for private pay bed patients of the upper middle and wealthy classes, by means of insurance and cash payments. All this with the tacit exclusion from participation in this branch of medical practice, with its experience and remuneration, of all medical practitioners except a selected few, called the visiting staffs. That is, a ring is being formed in medical practice. As you say, if this is allowed "the ranks of the younger consultants will be sadly thinned."

And so the fast foundering ship "Voluntary" goes lumbering on—under the delusion of making both ends meet by developing schemes each one of which turns out to be a financial loss. Then the British Medical Association, with an amused smile, hands out to all and sundry its panacea, put up in an easily handled form, guaranteed to cure timidity and nervous breakdown among the public and the State officials' stiff-neck among wealthy subscribers, blood impoverishment, deficient absorption, and malnutrition in the medical profession, especially among the visiting medical staffs hoarseness, brain-fag, run-down conditions, and sleeplessness among voluntary hospital administrators. "Use it, and all will be well." Is it not preferable that a real surgeon be called in?—I am, etc.,

HOVE SEPT. 7th

E ROWLAND FOTHERGILL

INSECT BITES AND RHEUMATISM

SIR,—In reply to the letter of Dr G. Arbour Stephens in the *British Medical Journal* of August 25th (p. 557), in which he mentions insects somewhat generally, and the human flea more specially, as the possible cause of rheumatic fever, may I refer him to the following papers I have written on the geographical distribution of the disease and of the common rat flea of temperate climates, *Ceratophyllus fasciatus*, with suggestions that this flea is the cause of the disease. *Indian Medical Gazette*, October 3rd, 1886, *Journal of Tropical Medicine* November, 1899, *Lancet*, 1915, vol. 1, p. 1160, *British Medical Journal*, 1922, vol. 1, p. 540, *British Medical Journal Supplement*, 1926, vol. 1, p. 202, *Proceedings of the Royal Society of Medicine*, February, 1928. Further investigation is required, but I think that I have shown a similarity in geographical, climatic, and other environmental conditions, both of this flea and of the disease, which may be more than coincidental. It is improbable that a specific disease would be caused by more than one insect.

The human flea, *Pulex irritans*, has not quite the same geographical distribution as that of *Ceratophyllus fasciatus*, and it seems to tolerate slightly higher temperatures, though not quite so low as those which can be withstood

by the rat-flea *Pulex irritans*, though not common, is found in some parts of the tropics, such as the Panama and in some of the southern Pacific Islands,² to which it was transported years ago. Although the geographical distribution of *Pulex irritans* is nearly similar to that of rheumatic fever, it would seem to be ruled out as a carrier by certain facts one of which is that it is so common that it would be more likely to be the cause of an epidemic disease such as scarlet fever than of an endemic such as rheumatic fever, although the geographical distribution of the two is almost identical. The structure of Aschoff's bodies is suggestive of their having been originated by a protozoan spirochaete, Rickettsia or allied organism rather than by a bacillus but it cannot be said that Aschoff's bodies are themselves protozoa.

It would seem that, if the possibility of this rat flea being the cause of rheumatic fever is accepted one of the important things to be investigated is the relation between the rat and the disease. There is said to be a relation between throat infections and rheumatic fever, but the throat condition may be either a symptom or a frequent concomitant of the disease, and the cause of the tonsillitis may enter a house through the same defective sanitary condition as does the flea-biting rat.

The work hitherto done on the environmental factors of rheumatic fever has been extensive though general and the cause has not yet been found. I agree with Dr. A. B. Stephens that the hypothesis that there may be a connexion between an insect and the disease is worthy of investigation.—I am etc.,

Harrow Aug 28th

J. TERTIUS CLARKE

Universities and Colleges

UNIVERSITY OF LONDON

THE Connaught Hall of Residence (14 Bedford Place London W.C.1) recently presented to the University of London by H.R.H. the Duke of Connaught will be ready for students of any of the colleges and schools of the University at the opening of the session in October. Mr. W. S. Angus M.A., LL.B., has been appointed warden, and Miss Barnett matron.

UNIVERSITY OF DUBLIN SCHOOL OF PHYSIC, TRINITY COLLEGE

THE Committee of the School of Physic, Trinity College invite every Lecturer in Ophthalmology for the next six months to undertake to prosecute study or research for a period of not less than six months in such place as the Board may approve and must during his year of office give an account of his research in a public lecture or lectures. The remuneration will be £150. Candidates must send their applications to the Registrar of the School of Physic Trinity College Dublin not later than November 1st and must state therein the work they propose to undertake and the place where they intend to carry it out. Applications should be accompanied by a statement of the applicant's qualifications and by a reprint of any published work.

ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW

SAMUEL MCMAHON, M.B. Ch.B. was admitted to the Fellowship of the Faculty after examination on September 3rd. As recorded elsewhere (p. 507) the honorary Fellowship was conferred on Sir Arthur Keith.

Medical News.

THE introductory address before the Middlesex Hospital Medical School will be delivered at 3 p.m. on Tuesday, October 2nd, in the Queen's Hall, by Mr. A. E. Webb Johnson, C.B.E., D.S.O., after which the prizes gained by students during the previous year will be distributed by H.R.H. Prince Arthur of Connaught, and Princess Arthur of Connaught will present the Fardon Memorial medals. The annual dinner will be held the same day at 7.30 p.m., at the Savoy Hotel, when the chair will be taken by Prince Arthur of Connaught.

THE annual dinner of past and present students of University College Hospital in this the centenary year of the Medical School will be held at the Hotel Cecil, Strand, on Friday, October 12th, at 7 p.m. The chair will be taken by Surgeon Rear Admiral Gaskell, C.B., F.R.C.S., Medical Director General R.N. Tickets may be had on application to the honorary secretary at the Medical School.

DR. T. WATTS EDEN will distribute the prizes at Charing Cross Hospital Medical School on Thursday, October 4th, at 3.30 p.m., in the out-patients' hall of the hospital.

THE annual dinner of past and present students of the Royal Dental Hospital of London will be held at the Trocadero (Empire Rooms) on Saturday, October 20th, at 7 o'clock, under the chairmanship of Mr. G. G. Camplin.

THE anniversary dinner of the Pharmaceutical Society of Great Britain will be held at the Hotel Victoria, Northumberland Avenue, W.C., on Wednesday, October 3rd, at 7 o'clock.

THE seventy-third annual exhibition of the Royal Photographic Society of Great Britain opens at 35, Russell Square, W.C.1, on September 17th and will continue until October 13th. Photomicrography is well represented, and the advancement in x-ray photography is illustrated by numerous exhibits.

THE Fellowship of Medicine announces that four post-graduate courses begin on September 17th, each lasting for two weeks. One in medicine, surgery, and the specialties will be given at the Westminster Hospital, occupying the whole of each day with lectures, demonstrations, and operations. A course in orthopaedics at the Royal National Orthopaedic Hospital, and another in diseases of children at the Queen's Hospital for Children, Bothal Green, will similarly occupy the whole of each day. The fourth course is one in diseases of the eye, which will be held at the Royal Eye Hospital, St. George's Circus, S.E., each afternoon at 3 o'clock.

THE Home Office, in communications dated September 5th, 1928, gives notice that the Secretary of State proposes, after the expiration of forty days from that date, to make Regulations under Section 7 of the Dangerous Drugs Act, 1920, for controlling the manufacture, sale, possession, and distribution of benzoyl morphine, dihydro-oxycodolone, and dihydro-codolone. The Regulations will be in the terms of Provisional Rules, dated September 1st, 1928, which, in accordance with Section 2 of the Rules Publication Act, will continue in force in the meantime. Copies of the Provisional Rules may be obtained on application to the Under Secretary of State, Home Office, Whitehall, London, S.W.1. The Home Office also announces, in the *London Gazette* of September 4th, that the Secretary of State proposes to make Regulations under Section 3 of the Dangerous Drugs Act, 1920, applying the Raw Opium Regulations 1921, as amended by the Regulations of 1922, 1923, and 1924, to coca leaves and Indian hemp.

A PARTY of Canadian medical practitioners interested in tuberculosis are at present travelling in Europe as the result of scholarships offered by the San Life Assurance Company. They have spent the last ten days in England, and have visited Liverpool, Birmingham, Cardiff, Winchester, Alton, Midhurst, and London, next week will be spent in France, chiefly in Paris. Other places to be visited during the remainder of September and the whole of October include Florence, Rome, Milan, Venice, Lysian, and, on the return journey to Canada, Cambridge, Edinburgh and Glasgow. The party is principally engaged in studying tuberculosis institutions of different kinds, it will attend the Conference of the National Union against Tuberculosis in Rome at the end of this month and that of the National Association for the Prevention of Tuberculosis to be held in October in London. During their visit to the King Edward VII Sanatorium at Midhurst, Sir St. Clair Thomson gave a lantern demonstration on his seventeen years' experience as a laryngologist to the institution. Dr. Pratten (London, Ontario) stated that every sanatorium in Canada had a laryngologist on its staff, and the larynx was now systematically examined in every case.

A COURSE of 56 lectures and demonstrations on diseases of the alimentary system, organized by Professor F. Gallart y Montés, will be held at the Hospital de la Santa Cruz y San Pablo of Barcelona from October 5th to December 10th. The fee is 100 pesetas.

THE tenth French Congress of Orthopaedics will be held in Paris under the presidency of Professor Nové-Jossard of Lyons on October 12th, when the following subjects will be discussed: sudden pathological dislocation of the hip, introduced by René Le Fort of Lille, and surgical treatment of flat foot, introduced by Alenbach of Strasbourg. Further information can be obtained from the general secretary, Dr. Paul Mathieu, 74 Rue Vanean, Paris (11^e).

MESSRS J. AND A. CHURCHILL announce for early publication *The Practice of Refraction*, by W. Stewart Duke Elder, D.Sc., M.D., F.R.C.S., Assistant Ophthalmic Surgeon, St. George's Hospital; *Diseases of the Blood* by A. Pinney, M.D., Research Pathologist, Cancer Hospital, London; *Recent Advances in Bacteriology* by J. H. Dible, M.B., Ch.B., Professor of Bacteriology, University of Wales; and *Clinical Chemical Pathology*, by F. S. Fowweather, M.D., M.Sc., Lecturer on Chemical Pathology, University of Leeds.

¹ Dunn. *Amer. Journ. Trop. Med.* 1923, liii, 33a.

² Buxton and Hopkins on "Researches in Polynesia and Malaya."

We are informed by Messrs Baillière, Tindall and Cox that they have undertaken the distribution in this country of *The Optum Problem*, by Charles Torry and others, of which a notice appeared in our issue of September 8th, page 450.

The July issue of the *West African Medical Journal* has a strong editorial interest, the contributions including articles on traumatic rupture of the spleen, multiple pregnancy, quinoline intolerance, tetanus, village sanitation, leprosy, and the Public Health and Medical Service in Nigeria. It will be remembered that this journal was inaugurated by the West African Medical Staff, and the directors of the Medical Research Institutes, at Accra and Lagos, together with the director of the Medical and Sanitary Service of Freetown, co-operate in its production. Copies of the journal may be obtained from the Director of the Medical Research Institute, Lagos, Nigeria, the annual subscription is 20s.

The International Congress against Alcoholism held at Antwerp from August 20th to 25th was attended by about 400 members from 32 different countries. The programme included papers on alcoholism as an international problem, alcoholism in Russia, personal liberty, prohibition in the United States, the Bratt system of liquid control, liquid laws of 1919, the action of alcohol on the offspring, alcohol and spas, alcohol and sunlight, welfare centres for drinkers and non-alcoholic beverages. The next congress will be held at Warsaw in 1931, by invitation of the Polish Government.

According to the *Journal of the American Medical Association* during the last three years there has been a progressive decline in typhoid fever in the great cities in the United States with a population of more than 100,000. In 1927 five of the eight geographical groups had typhoid death rates under 2 per 100,000 and the other three groups had rates varying from 3.39 to 10.07.

Letters, Notes, and Answers.

All communications in regard to editorial business should be addressed to **THE EDITOR, British Medical Journal, British Medical Association House, Tavistock Square, W.C.1**

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated. Contributors who wish notice to be taken of their communications should authenticate them with their names and addresses.

Authors desiring REPRINTS of their articles published in the *British Medical Journal* must communicate with the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W.C.1, on receipt of proofs.

All communications with reference to ADVERTISEMENTS as well as orders for copies of the *Journal*, should be addressed to the Financial Secretary and Business Manager.

The TELEPHONE NUMBERS of the *British Medical Association* and the *British Medical Journal* are: **MUSEUM 9561 9562 9563 and 9564** (internal exchange, four lines).

The TELEGRAPHIC ADDRESSES are: **EDITOR of the British Medical Journal, Antiology Westcent London**.

FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.) **Articulate Westcent London**.
MEDICAL SECRETARY **Medicera Westcent London**.

The address of the Irish Office of the *British Medical Association* is 18 South Frederick Street, Dublin (telegrams **Dacillus Dublin** telephone 62550 Dublin) and of the Scottish Office 7 Drumsheugh Gardens Edinburgh (telegrams **Associate, Edinburgh** telephone 24361 Edinburgh).

QUERIES AND ANSWERS.

TREATMENT OF COLI BACILLURIA

"I. M. S." asks for suggestions for the treatment of coli bacilluria in a lady who has had large doses of antiseptics and has taken hexamine caproate and hexyl resorcinol for lengthy periods. She has also had great quantities of potassium citrate, potassium bicarbonate and other alkalis and gallons of Coutréville Vichy, and distilled water, without the slightest improvement. The urine remains highly acid, and gives a heavy growth of *B. coli*. Crystals of calcium oxalate were present in the last specimen of urine examined. Her gall bladder was removed two years ago, and the *B. coli* infection was detected six months later. She suffers from severe headaches, but is otherwise in good health.

SUNSTROKE IN GREAT BRITAIN

"W. J. B. S." asks where information can be obtained about the effects and treatment of the mild sunstroke sometimes experienced in Great Britain. One effect is that the patient is upset by being out in the sun though previous to the stroke this did not cause the unpleasant cephalic symptoms.

VAGINISMUS

SUGGESTIONS in response to "C. A. S." inquiry (September 8th, p. 473) have been received from several correspondents. "J. A. C." regards the case as essentially one for treatment by psychotherapy rather than by surgical measures. "H. M. L." also believes that cases of this kind are usually of psychical origin, and advises consultation with a medical psychologist with a view to analytical treatment, in his opinion hypnosis is unlikely to prove successful, as the condition may have several other elements. "W. H. M." suggests that artificial lubrication under anaesthesia immediately after a period would produce *ejaculation* and cure the condition.

MOUTH BREATHING

Dr. W. E. H. BULL (Hunstanton) writes in answer to "School Medical Officer" (September 8th, p. 477) that the cause of a child who is a mouth breather is an apparatus quoted from a paper of the London Hospital Medical Society on October 30th, 1913, by Mr. G. Northcroft, at that time senior dental surgeon to the London Hospital. And if any operation for adenoids is undertaken instruct them in acquiring the habit of nasal breathing by daily breathing exercises, and at night wearing an anti-mouth-breathing metal valve which keeps the mouth moist and clean, and absolutely prevents a reversion to oral breathing. This apparatus will also be found of great utility in the treatment of adults, and all rhinologists should advise its use.

Mr. WRIGHT LAWRENCE M.R.C.S. L.D.S. writes: When I was a student at the Royal Dental Hospital we used to make a light wire frame in the form of an internal dental splint, over which was stretched thin sheet rubber to correct the habit of mouth breathing. The appliance was worn during the night.

STATUS EPILEPTICUS

"H. C. B." writes in the *British Medical Journal* of July 7th (p. 40), in reply to a query by me the week before, Dr. L. Harris Liston advised giving hyoscin hydrobromide gr. 1/100 hypodermically for this condition. I have found this treatment of the utmost value and I think it should be widely known. That this is not so at present is evident from the fact that no mention is made of it in Muskoka's recent book on epilepsy or in Dr. Collier's 1928 Lancelot Lectures. Paraldehyde per rectum, strongly recommended by Dr. Collier, was quite without effect in my case, but I have had no other experience with it.

INCOME TAX

Commencement of Appointment

"R. M. L. S." terminated a short engagement in the Royal Navy on March 2nd, 1928, as from which date he commenced hospital duties. Is he liable for 1928-29, seeing that his income was taxed by deduction for 1927-28?

* Yes, the change in the nature of the appointment held necessitates a new departure in the assessment of his income, and he is liable to tax for 1928-29 on the amount of his income for that year.

Research Scholarship

"D. B." is the holder of a research scholarship of £150 for the year 1927-28, but owing to illness, the scholarship is being held over till this winter session. Is this income liable to tax?

* The exemption of scholarships from income tax was provided by Sec. 28 of the Finance Act, 1920, and applies to "income arising from a scholarship held by a person receiving full time instruction at a university, college, school, or other educational establishment", a "scholarship" is defined as including an exhibition, bursary or other similar educational endowment. On the whole, it is difficult to bring a research scholarship of the nature referred to within the condition that the holder shall be "receiving full time instruction" especially in view of a decision in a recent case (*Henslip v. Hasemer*) which suggests that mere oversight of study does not constitute full time instruction.

Expenses Incurred by Locumtenent

"D. C." has been doing locumtenens work during the past year, and inquires whether he can deduct hotel expenses in making his return.

* The Income Tax Acts forbid the deduction of any disbursements or expenses not being money wholly and exclusively laid out for the purposes of the "profession". Hotel expenses are in the main "laid out" for private purposes, and seem strictly to come within the above prohibition. But we have been given to understand that commercial travellers and other persons compelled by their vocation to move from one hotel to another are allowed to deduct some portion of their expenses as representing the additional expenditure caused by the nature of their work. Perhaps "D. C." can discuss the matter with his Inspector of taxes and obtain some relief on that basis.

LETTERS, NOTES ETC

MERCUROCHROME

MR. R. W. E. STICKINGS OBE, B.Sc. (Wandsworth, S.W.), writes in the *British Medical Journal* of August 11th p. 238 there appears an article on 'Mercurochrome 220 soluble' by Sir William Pope and others, in which a comparison is made of various trade samples of mercurochrome with a "standard" sample prepared by Messrs. British Colloids Ltd. We must admit that the general conclusions drawn are in agreement with our own findings but we think it unfortunate that among the trade samples analysed only one sample even approached the "standard" preparation in its conformity with the theoretical composition of disodium dihydroxymercuri fluorescein. We are also surprised that all the four samples analysed contain such a high proportion of water eliminated at 110°C *in vacuo*. Admittedly, the preparation of mercurochrome on a large scale presents several difficulties as the starting material, fluorescein, is itself not easy to obtain in a state of absolute purity. Moreover dihydroxymercuri fluorescein, whilst it may be recrystallized on a laboratory scale, is very insoluble in the ordinary solvents in commercial use. After this stage the intermediates and finished product are not crystalline, so that simple methods of ensuring purity are not then available. In spite of this it is possible to get a close approximation to purity at each stage, and only by doing so can a mercurochrome approximating to the theoretical composition be produced. In the final stages of the manufacture—that is the formation of the solid sodium salt—care has to be taken to avoid decomposition as it is easily possible for inaccurate methods to cause decomposition of metallic mercury in globules from a perfectly bright solution. But we are of opinion that from the point of view of stability a moisture content of 10 per cent is not desirable in the finished product, and there appears no valid reason for its presence. In confirmation of this an examination of two samples of British made mercurochrome (Messrs. May and Baker, Ltd.) showed a moisture content of 2.8 per cent and 2.6 per cent respectively after four hours at 110°C *in vacuo* whilst another sample of a well known American brand contained as much as 12.6 per cent under the same conditions. The samples of British manufacture contain 27.4 and 25.8 per cent mercury, and 22.1 and 21.2 per cent bromine respectively. Both the mercury and bromine figures vary less than 1 per cent from the theoretical figures, and to maintain a closer approximation to theory than this in the manufacture of hundred weights of this substance is little short of impossible. The toxicity of this material is tested as a routine on rabbits and a consistent toleration of between 20 and 30 mg per kilogram of body weight is manifested.

MALIGNANCY AND THE ENZYME

LIEUT. COLONEL V. N. WHITMORE I.M.S. (Sialkot, Punjab) in a note dated August 10th writes. It would be of interest to know what, if any investigations are being made by the Cancer Research Committee as regards tissue and *in vivo* cell enzymes, both intra and extra-cellular as a likely factor in the irregular mitosis of the malignant cell. Is the "specific factor" of Gye and Barnard the malignant cell enzyme, and the ultra-microscopic virus the broken down or separated mitotic material, and is the unlimited potentiality of growth due to continued catalysis of malignant cell enzyme associated with the absence of the anti-enzyme? The vital role of the enzyme in the chemical physiology of cell life leads one to assume its importance in the equilibration essential to regular mitosis and a defective or altered enzyme to a replacement of a normal cell by a spurious prototype with the embryonic potentiality of rapid and irregular karyokinesis. The accepted fact—accepted beyond all reasonable dispute—that the origin of malignancy is local presupposes also that the normal physiological metabolic processes in the cell are being unduly stimulated by a definite factor or enzyme, that the life-history of a normal cell depends on its own ability to conform physiologically and solve its own bioplasmochemistry—in other words to activate its enzyme (and anti-enzyme) and thus ensure a metabolic equilibrium and physiological karyokinesis. It is also a fair assumption that the greater the metabolic and physiological activity of the cell the greater the liability of the normal cell enzyme to become defective. The complex physical properties of enzymes, including reversibility of action and catalysis probably due to two factors, are to some extent understood, at all events, to a greater extent than their chemical properties. It is fair to assume that the normal physiology of cell life when interfered with by any influence acting locally be it an hereditary (endocrine) factor, an autotoxin or persistent focal dehalization the result of persistent irritation, or deficient trophic influence should be so altered as to affect fundamentally the normal properties of the enzyme on which the physiological metabolism of the cell including mitosis depends. The hypothesis of such a theory appears a justifiable one and that the processes of life itself, which Sir Lancelot Cheate suggests must be probed before an adequate solution is found, is but a higher evolutionary form of a continuous biochemical reaction.

MEDICAL TREATMENT IN CHINA.

DR. O. MARRIOTT (Haywards Heath Sussex) writes in reply to Fleet Surgeon Home's inquiry (August 4th p. 228). With the experience of twenty years' practice in Hong Kong where I had a very considerable number of Chinese patients and had several Chinese families as contract patients I have repeatedly inquired especially of the intellectual classes who should know whether there were any grounds for this constantly repeated

story by Europeans—more especially by globe trotters—that the Chinese paid their doctors a fee while in health and suspended payment if they became ill. All those asked stated that there was no such custom. They sometimes admitted having heard of it, but only from Europeans asking about it. I am convinced that among Chinese in the south—that is, Kwang Tung—there is no such custom. Globe-trotters repeat such fables as this so often on their tours that when they come home and write their 'book' they really believe they are true.

DR. T. H. JUDD (China Inland Mission) writes I may say that I never came across the alleged Chinese custom of paying fees to their doctors while well and discontinuing them when ill, although I was a medical missionary in Kiangsi Province more than twenty years.

THE PREVENTION OF TUBERCULOSIS.

DR. W. HOPKINS ASHMORE (Monkstown, Dublin) wishes it to be known that the point he made in the discussion by the Section of Tuberculosis at Cardiff was that the practice of collecting sweepings of rooms in which tuberculous patients are being nursed, and the piling of this dust on an open dump, is a very definite factor in the spread of tuberculosis. He advocates the incineration of all house refuse as a remedy to the diffusion of infectious diseases. He writes: It is quite incomprehensible to me why in view of our present knowledge of bacteriology, we still persist in the daily practice of collecting the sweepings of rooms in which are patients suffering from tuberculosis, measles, scarlatina, diphtheria, and typhoid fever, and of spreading this dust on an open dump which is frequently situated in a convenient place beside the main road, or in the centre of a thickly populated suburb.

LORD HALDANE'S DEFINITION OF THE "EGO" OR "SELF"

SURGEON REAR ADMIRAL CHARLES M. BEADNELL, R.N. (ret.), writes. In your note in the *Journal* of August 25th upon Lord Haldane F.R.S., you make no allusion to his excursions into the realms of psychology. The distinguished statesman philosopher was, as is well known, an ardent Hegelian and in his Gifford Lectures of 1902-3 he made a somewhat desperate attempt to reconcile with the tenets of modern science the topsy-turvy doctrine of the great German metaphysician that reality is identifiable with thought. I think few, if any, modern scientists would admit the success of a venture which involved even Lord Haldane himself in contradictions. In his *Pathway to Reality*, the title under which the lectures were published he states (p. 31) 'In the universals of thought, and not in the impressions of sense, are to be discovered the true foundations of the world. Thought rather creates things than things thought.' *Esse was for Haldane, Intelligi, not Percipi.* I think the general verdict of modern science rather is *Nihil est in intellectu, quod non prius fuerit in sensu, nisi ipse intellectus*. Quite in keeping with his idealism was his famous definition of the subject of thought, the thinker the "Ego" or "Self" and it should be carefully contrasted with his words as quoted above. He states (p. 154) "If you look quite simply into your own bosom and try to find out what your Ego is you will find that you have embarked upon a very difficult task. Your Ego comes to disclose itself as a mere asymptotic regress towards a notional pure subject of knowledge—a thinker without thoughts an abstraction, nothing at all." Such a definition whittling away the Self into nothing is surely at variance with the contention that thought is the reality. The definition has been welcomed by a certain school of psycho-analysts, but to the average mortal will, I opine prove unacceptable. On the one hand, the most modest and self-effacing will find it somewhat unappreciative and on the other hand those who like Kipling's cat, have too much Ego in their cosmos and prefer to walk by themselves, will regard it with severe displeasure.

HOMOEOPATHIC CONGRESS

DR. F. B. JULIAN (Liverpool) writes. The British Homoeopathic Congress, which is meeting this year at Liverpool, will devote its business sessions to a symposium on gastric and duodenal ulcer. The sessions will be held in the surgery theatre of the University by kind permission of the Dean of the Medical Faculty and papers will be contributed from the general medical, surgical, pathological, and homoeopathic standpoints. The Congress meetings are on September 21st, commencing 9.45 a.m.

LITTER.

DR. H. MURDITH (Wellington Somerset) writes. Yesterday, in the Doone Valley there was—as is usual in beauty spots—a lot of paper etc., lying about. The most glaring piece was an envelope addressed to M.D. of Hendon and around were advertisements of Wampole. Surely the medical profession ought to be the first to discontinue such things. If M.D. throws his correspondence about like that I wonder what he does with his sandwich wrappings. No wonder private owners are closing their estates to the public.

VACANCIES

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals will be found at pages 45, 46, 47, 50, 51, and 52 of our advertisement columns, and advertisements as to partnerships, assistantships, and locumtenencies at pages 48 and 49. A short summary of vacant posts notified in the advertisement columns appears in the *Supplement* at page 135.

Remarks

OR

ACUTE NEPHRITIS

BY

T CHILMAN MOORHEAD, M.D., F.R.C.P.I.,
Regius Professor of Physic Dublin University

INCIDENCE

It is generally believed that acute inflammation of the kidneys is a rare disease. In civilian practice it is certainly rare, except as a complication of scarlatina. The figures given by Herringham in his book on kidney diseases (1912) are often quoted. He states that only 166 cases were treated at St Bartholomew's Hospital out of about 63,000 admissions during a period of nine years.

Reference to the Registrar-General's reports shows that in the five years 1822 to 1826 inclusive the total number of deaths from all causes registered in the Irish Free State was 314,829. Of these, the total number registered as from acute nephritis was 1,362, of which 645 were in females and 717 in males. These figures include all deaths from acute nephritis in adults and all deaths from nephritis in children under 10 years of age, but do not include deaths from eclampsia. These figures show that one death in every 231 registered is reported as due to acute nephritis. The deaths registered as due to chronic nephritis during the same period numbered 6,143.

In England and Wales during the same years (1822-26) the total number of deaths from all causes registered was 2,231,445. These included 6,964 classified as acute nephritis, of which 3,288 were in females and 3,676 in males. This gives one death from acute nephritis in every 334. The deaths registered as due to chronic nephritis during the same period numbered 56,146. If we assume that there is an immediate 10 per cent mortality from the acute disease (and this is probably higher than what actually occurs) the number of cases treated in any one year in either country can be easily calculated.

Owing to the comparative infrequency of the disease no systematic study of groups of cases was possible until the great war. Then, as is universally known, nephritis occurred in epidemic form, and under conditions where close observation, both of immediate symptoms and remote consequences, was possible. The result is that our knowledge of the disease has greatly increased of recent years, and we now perhaps realize more fully than formerly that many deaths recorded as due to chronic nephritis are the late sequelae of acute nephritis.

PROPHYLAXIS

The best way to avoid on attack of nephritis is to shun those conditions which render the individual specially liable to it, but in spite of every effort many people will continue to suffer from scarlatina and other infective conditions, and many will be far from anxious to avoid pregnancy. The question, then, arises as to whether anything can be done to decrease the incidence of nephritis in such conditions. It is quite unnecessary to refer to the common sense precautions which ordinary clinical experience will dictate, and which should, above all, be observed by those already suffering from chronic renal disease.

The recently acquired knowledge that septic tonsils and septic nasal sinuses may be the source of toxins which can produce acute damage in the kidneys suggests at once that the removal of such tonsils and adequate treatment of such nasal diseases may be looked upon as a preventive measure. In scarlatina it was the fashion some twenty years ago to prescribe urinary antiseptics of the hexamine type, and many statistical records were published to show that the incidence of nephritis was lessened in cases in which these drugs were given. The passage of time has not confirmed these records, however, and few clinicians now believe these antiseptics to be of any value.

A new impetus to preventive measures has been given by the researches of Osman, who, as a result of careful study in collaboration with others, has stated recently that the incidence of nephritis after scarlatina is greater in those whose urine is unduly acid and in whom the alkali reserve of the blood is diminished. He and his co-workers also claim to have reduced the incidence of nephritis after scarlatina to 0.6 per cent in 620 cases treated by alkalis, as compared with 5.5 per cent incidence in 316 cases not so treated. If these results are confirmed it may be advisable to employ alkalis in future in all cases of scarlatina, and to extend Osman's observations to other diseases, not excluding pregnancy, in which nephritis is a frequent incident. Large doses are, however, required, and it is possible that many patients will object to their consumption. At present Osman's conclusions must be received with hope, but with caution. Peters, in an analysis of nearly 8,000 cases treated between 1910 and 1927, found no significant difference in the onset of complications in those treated with and without alkalis respectively, and Stigglitz goes so far as to say that excessive intake of alkalis may actually predispose to nephritis instead of the reverse.

The value of scarlatinal antitoxin is still *sub judice*, but the reports up to date are fairly satisfactory. Gardner Robb states that in 100 cases of average severity treated by serum no case of nephritis occurred, and there is no reference in his paper to even the occurrence of albuminuria. On the other hand, Dr Burns, a former pupil of mine, tells me that the experience at the City Hospital, Liverpool, is that scarlatinal antitoxin does not diminish the incidence of complications.

CLASSIFICATION

Innumerable attempts have been made to classify the different forms of nephritis, but fortunately the limitation of my subject to acute nephritis renders it unnecessary to attempt anything but the very simplest, indeed, from my point of view, much time has been wasted in the attempts that have been made to divide and subdivide, instead of recognizing the unity which underlies the varying pathological manifestations of the acute condition. It is, however, necessary to state that under the term "acute nephritis" I include not merely acute non-suppurative inflammations of the kidney, but also acute non-suppurative degeneration. In short, I do not intend to use the word "nephrosis" as indicating a condition distinct from acute nephritis. The term "nephrosis," indeed, has not been generally adopted by English writers, though it is employed largely in Europe and the United States to designate a clinical and pathological entity of acute origin characterized by primary degeneration of tubular epithelium, unaccompanied by inflammatory phenomena. Even if this condition does exist in the pure state, I am convinced that it is wiser, both for the sake of clarity of thought and also for diagnostic and teaching purposes, to include it merely as a variety of acute nephritis. This remark, of course, applies to the condition known as toxic kidney, a term which is becoming increasingly frequent in the English literature to describe a state identical with nephrosis.

Classifications have been attempted on the basis of etiology, pathology, clinical symptoms, and on that of disordered function. Provided, however, that we remember that the kidney is composed of four elements—glomerular, tubular, interstitial, and vascular—and that each element may be involved in a varying degree according to the cause of the inflammation, its severity, and its duration, and provided we remember that the functional changes are likely to vary also with the degree of involvement of each of these structures and the severity of that involvement, we will do better as clinicians to recognize one form of acute nephritis only. The only exception that I can see to this view is the acute nephritis which is met with as a complication or symptom of ulcerative endocarditis. It must, of course, be remembered that acute inflammation may attack not merely a healthy kidney, but also a kidney damaged to a greater or lesser extent by previous disease.

[3533]

SYMPTOMATOLOGY

The symptoms are too familiar to require enumeration. They vary in severity from transitory febrile albuminuria to the most acutely fulminant manifestations. It is customary to distinguish a variety characterized mainly by oedema from a variety in which haemorrhagic urine is the predominant symptom, and it is even contended that parenchymatous lesions with resultant oedema are more particularly likely to be produced by staphylococcal toxins and glomerular lesions with haemorrhage by streptococcal toxins. The evidence for this is, however, far from convincing, and my own experience is that oedematous and haemorrhagic cases are by no means invariably clear-cut. A rise in blood pressure was at one time regarded as almost certain evidence of old-standing nephritis. It is now, however, universally recognized that even in primary acute attacks of every variety the blood pressure may rise rapidly. As a fall in blood pressure accompanied by diminution in size of the heart is a favourable sign, it is important to take systematic sphygmomanometer readings throughout. Diagnosis can hardly ever be in doubt, except in the very rare cases of complete anuria with palpable swelling of one or both kidneys, and with delayed appearance of oedema. This was met with in the cases described by Reginald Harrison in which surgical treatment was undertaken under the impression that cases of acute hydronephrosis were being dealt with. One case of this type was that of a lady, aged 35, whom I saw in consultation some years ago. Her history was as follows:

After a day of active exercise she woke in the middle of the night with severe pain in the back and much restlessness. The next morning she was slightly feverish, was unable to pass urine, and presented a distinct tumour in the right renal region. I saw her two days later in conjunction with her medical attendant and a surgeon. In the forty-eight hours since the beginning of her illness not a single drop of urine had been passed nor could any be obtained by catheter. She was feverish and restless and on her right side a tumour, diagnosed as an enlarged kidney, was easily detectable and was extremely tender on pressure. X-ray examination was out of the question; the diagnosis reached was acute calcareous hydronephrosis with reflex cessation of function of the left kidney. As no improvement had taken place next day and as no further symptoms had appeared, operation was agreed to, but on exposing the right kidney, no stone and no hydronephrosis was found. The kidney was much enlarged, and on incising the capsule bulged out as if under extreme tension. On the next day a small quantity of urine was passed; it was found to be loaded with albumin and contained blood and granular and epithelial casts. After a hesitating course uraemia developed ten days later and the patient died. Prior to death she developed generalized oedema and other ordinary nephritic symptoms. It was only possible to remove the right kidney for examination and this was found to show pronounced glomerulotubular nephritis.

CHEMISTRY

In a case of average severity the condition of the urine is familiar. It is scanty, probably owing to the diminished blood flow brought about by the general vascular congestion, and contains blood, casts, and abundant albumin. It is generally assumed that the albumin is entirely composed of blood protein filtered through the glomerular membrane, but a recent study by Kellaway, Davies, and Williams suggests that when the cells are severely damaged much of the protein present consists of kidney substance. Further work on the proteins of urine is desirable. The quantity of albumin diminishes as the patient improves. Acute nephritis is, indeed, one of the few conditions in which regular estimation of the amount of albumin passed is of value. Incidentally, however, it may be stated that estimations by the Esbach albuminometer are even less reliable than is generally believed. In a recent study Geoffrey Bewley has reminded us that the readings of that instrument vary widely according to the temperature. Thus, the same specimen of urine on two successive days will vary as much as 25 per cent according to the temperature of the day. In fact, the ordinary heat and acetic acid test in most cases enables one to judge just as satisfactorily as does Esbach's instrument. The men present is diminished in the early stages, and chlorides may be reduced almost to vanishing point. Diastase also is lessened, except in the nephritis of eclampsia.

In conformity with the condition of the urine certain blood changes are found. Urea is almost invariably increased, and in cases which do not progress favourably very high levels of blood urea may be reached. As improvement sets in and diuresis occurs the urea rapidly returns to normal. It is admitted that the progress of the case and the immediate prognosis may be better determined by blood urea estimation than by any other laboratory examination.

The chloride in the plasma is probably increased in the early stages, although opinions vary greatly on this matter, and the whole question of chloride excretion and chloride retention is one that must be approached with much humility. Some writers believe that chloride retention in the body is due to a definite renal failure to excrete chlorides. Others regard it as merely secondary to the failure on the part of the kidney to excrete water. Still others believe that chloride retention arises in a totally different way. They hold that in acute nephritis the permeability of the capillaries throughout the body becomes increased as the result of the presence of toxins in the circulatory system, and possibly as a result of diminished surface tension of the serum, and that this increased permeability, combined with the hydraemia resulting from oliguria, leads to a great outpouring of fluid into tissue spaces. This fluid must contain its normal quotient of sodium chloride, and hence there results a locking up of chlorides in the body, due to tissue demand rather than to renal failure. The actual chloride is of importance, and many now feel that the sodium ion is more important than the chlorine ion. In favour of this view the beneficial effect of calcium chloride and ammonium chloride in producing diuresis is often referred to.

Through these tangled views it is hard to find one's way, but the fact remains that there is considerable chloride retention in the body as a whole. Other blood changes include the existence of a slight acidosis due to a diminution of the sodium carbonate blood content. The existence of this was foreshadowed long before the days of biochemistry by clinicians, who found that it was more difficult to make the urine alkaline in acute nephritis than in health, and who believed that once it was rendered alkaline the danger of the onset of uraemia was almost certainly averted.

Fischer's theories may here be referred to briefly. He believes that local alterations in the acidity and alkalinity of tissues produce changes in hydration, inasmuch as a changed reaction alters the capacity of the body colloids to hold water. Many of the actual changes found in the kidney cells are explained by him in this way, but the theory, though attractive at first sight, has been proved untenable. In my hands the treatment of renal cases by Fischer's strongly alkaline solution has not proved satisfactory.

Blood phosphates are also increased, and are stated to be closely associated with the development of toxic symptoms. A return to normal is of favourable significance. On the knowledge that a deleterious phosphate retention exists is based the treatment by calcium salts, and von Noorden's special recommendation that large quantities of calcium should be given to all nephritic patients who are taking much milk. Milk, as is well known, is rich in phosphoric acid.

Maxwell has found that cholesterol also is increased in the blood in acute nephritis, and although other observers have stated the contrary, his work seems sufficiently definite to establish the fact. He asserts that, as the patient improves, oedema first disappears, then excessive cholesterol, and then albumin. From the practical point of view, however, cholesterol estimations are at present unimportant.

If the patient progresses from an acute into a subacute stage, further blood changes in the nature of argaemia and diminished protein content, with possible changes of albumin-globulin ratio, may take place, but these do not require discussion.

Coincident with the changes in the blood and blood pressure, various changes occur in the cerebro-spinal fluid. The actual pressure of the fluid is increased, as evidenced by the fact that when a lumbar puncture is done it squirts out under considerable pressure. Analysis of the fluid will

show increase of urea, increase of protein content, and, according to most writers, a considerable increase of chlorides, especially if uremia is threatened. It is even said that a high chloride level is diagnostic of the onset of uremia.

FUNCTIONAL KIDNEY TESTS

Since the days of Bright progress in our knowledge of the nephritides has been steady, but comparatively uneventful. Gradually improving microscopical technique has added much bulk to the literature, and has succeeded in differentiating fairly satisfactorily, and with almost painful accuracy, the stages and varying types of nephritis. With the coming of biochemistry a new chapter has been opened, and with the ever-increasing progress of this science we are now in a position to make not merely a guess at the anatomical state of the kidneys in any given case, but to estimate with some certainty the degree of impairment of their physiological function. It is, however, important for the clinician to remember that functional tests should not displace either chemical examination or judgement based on careful observation and examination of the patient. In acute nephritis, indeed, most of these tests are of little importance till the acute stage has passed, but in the recovery stage, particularly if recovery is delayed, they may be of much value in prognosis and in estimation of residual kidney damage. The tests must be repeated again and again, and found to give consistent results, before they can be relied on. A single functional test is valueless, and may be misleading. Further, these tests do not always give us information concerning one only of the four parts of the renal mechanism. For example, the urea concentration test may show defective function either because too little water is absorbed from the tubules, or because the glomerular membrane and the tubules do not permit the passage of a normal amount of urea. On the other hand, the dye tests probably afford information concerning the epithelial cells alone, and when benzoates are given with the object of testing how much hippuric acid will be formed, we are determining the power of the interstitial tissue to form that substance, and the power of the cells to excrete it.

COURSE AND PROGNOSIS

Provided no complication shows itself by far the largest number of cases of acute nephritis pursue a favourable course, though not necessarily to complete recovery. In an average case, after a few days, the original oliguria gives place to diuresis, and, coincidentally with this, the oedema begins to disappear. In my own experience in adults those cases which present the greatest amount of blood in the urine at the beginning recover most rapidly. In the most favourable cases within a month no trace of the disease may be left. The actual percentage of cases in which permanent damage—either stationary or progressive, and either mild or severe—is left has been estimated differently by various observers. Do Wesselow, for example, estimated in war nephritis that 70 per cent had completely recovered after the lapse of a year, while Humo and Nattrass, in a recent study, refer to the fact that in France 77 per cent were found normal after the same period. On the other hand, these last named state, as the result of their own observations on 281 cases seen during the years 1922-25—that is, over a period commencing four years after the termination of the war—that only 45.5 per cent had no evidence of renal disease, 9.5 per cent had advanced chronic nephritis, and 2.5 per cent had died, while 43.5 per cent showed evidence of some permanent damage to the kidneys, and were believed to be developing advanced chronic nephritis.

In watching cases one of the most important things to consider is whether the subacute or chronic process is or is not going to supervene on the acute. It has probably been the experience of everyone to meet with cases in which albumin has completely disappeared from the urine after persisting for as long as twelve months or more, but this is exceptional, and in general it may be assumed that if albumin is still present after the lapse of six months, complete restoration to health is unlikely. In estimating prognosis we must of course consider whether we are or are not dealing with an exacerbation of a pre-

existing nephritis. It is in these cases that the functional tests are of so much value. Some writers go so far as to say that, provided such tests show a normal response, the presence of albumin is of no consequence whatever. With this view I cannot agree. My experience is that no matter what response patients may show to tests, if albumin is persistent they remain below par, and are particularly liable to intercurrent infections.

TREATMENT

In the early stages rest is imperative, and should be insisted on as long as haematuria persists. In cases with oedema and fairly abundant albumin I have often found improvement follow getting the patient up. Each case must be judged on its merits, but in general I am opposed to overdoing the period of rest in bed.

As regards diet, most patients at the beginning of the illness suffer from anorexia, and some from nausea and vomiting. This automatically limits the intake of food. As von Noorden long ago pointed out, even water should not be pressed at this stage, and whatever theories we may hold, it certainly seems advisable to limit also the intake of chlorides. Small quantities of milk and water to which a little calcium carbonate has been added satisfy all necessities. As improvement sets in, carbohydrates may be added fairly freely, always having regard to the digestive powers of the patient. Grapes and fruit juices, including fruit jellies, are appreciated, and gradually proteins may be increased. The revolt against the consumption of large quantities of milk in this stage, on the ground of its large protein and water content, took place during my student days, and at once appealed to common sense. Even when almost complete recovery has taken place it is well to maintain some restriction regarding proteins, though one admits with Wordley that no direct increase of albumin results from an increased protein intake. In later subacute stages the problem may alter, and Epstein's diet be required.

As regards other measures, the old-fashioned hot pack and the more newly devised radiant heat bath seem temporarily to be under a cloud. In stating this I cannot help recalling the old-fashioned suggestion to rub the skin with bacon fat in order to prevent sweating, and so to leave more fluid in the body for the purpose of flushing the kidneys. Indiscriminate sweating is, I am sure, weakening, but when headache and other uraemic symptoms threaten, I have not the least doubt that a good radiant heat bath is beneficial. It is seldom that in any stage direct measures for the relief of anasarca will be required, but, if they are, Southey's tubes are undoubtedly preferable to multiple punctures.

No drug treatment, apart from the giving of mild diaphoretics and purgatives, is required at first. All stimulants of the kidney must, of course, be rigidly barred. Later, with hydraemia, and with excess of urea in the blood, these may be tried, in the hope of promoting diuresis. I have tried ammonium chloride, so strongly recommended from the Mayo Clinic, but without good results, and the equally strongly recommended novasural is unquestionably a substance to be used with caution. In my experience it is a much safer remedy in cases of cardiac than of renal oedema.

Decapsulation

In 1896 Reginald Harrison put on record three cases of acute nephritis in which cure had followed incision and stripping back of the capsule. Later he reported further cases, and stated that operation was indicated (1) in cases of acute nephritis in which convalescence is delayed, and in which albumin and casts do not disappear from the urine, (2) in cases where suppression of urine occurs, (3) in cases where marked cardiac and circulatory disturbances arise in the course of inflammatory renal disorders.

In 1903 Edebohl suggested a similar operation in more chronic cases of nephritis, with the object of preventing compression of the kidney and of establishing collateral circulation, and more recently Roosing (1922) has recorded 69 cases of nephropathy grouped under four headings, for which decapsulation was performed with apparently good results.

The reasons for such an operation are quite different in an acute and in a subacute stage. In an acute stage, when the capsule is incised the kidney bulges out, and therefore it might be claimed that relief from tension is afforded. In practice, however, the operation seems to have been generally abandoned, and inasmuch as most cases pursue a favourable course on ordinary lines such a serious procedure is never justified. In the subacute cases the capsule has adapted itself to the increased size of the kidney, and operation can only be justified on the plea of establishing collateral circulation, and thereby arresting a progressively downward course. Most physicians who realize that recovery from an operation does not always mean cure of a disease, and who realize the many variations in course taken by subacute nephritis, will hesitate long before recommending surgical intervention. In a recent paper, however, Fawcett urges the value of the operation in a specially selected group of subacute parenchymatous cases, the sequelae, for the most part, of acute inflammation.

When uraemic coma develops, either subsequent to or independent of epileptiform convulsions, and when all ordinary measures such as hot packs, the use of pilocarpine in small doses, and purging fail to produce rapid improvement, venesection should be performed. I well remember the first case upon which I performed venesection, some twenty-five years ago.

A boy, aged 18, was admitted suffering from acute nephritis. After a few days he was well on his way to recovery. At this stage his friends managed to bring in a large supply of food and the boy enjoyed a surreptitious but hearty meal. That evening he had a severe convulsion and passed into a state of coma. During the next day the coma persisted and there was almost complete anuria. The next morning thirty-six hours after the beginning of the coma he was still deeply unconscious, and apparently going downhill. I bled him to the extent of about 15 oz. a few hours afterwards he opened his eyes and that evening he again became conscious, and ultimately made a good recovery.

When bleeding a serious case, if the blood flows badly, it is worth remembering Landei Brunton's tip that inhalation of oxygen will make the blood less treacherous and greatly facilitate procedure. It is curious that some writers, such as Tweedy, regard bleeding as dangerous in eclampsia, but most gynaecologists are in favour of moderate venesection.

During the war I practised lumbar puncture in addition to venesection for the repeated convulsions that were so frequently encountered. The most recent writers seem to regard lumbar puncture as a mistake, but I am convinced that no harm ever resulted in my own cases, and, judged as a clinical procedure, it appeared to have a beneficial result. It seems, indeed, to be a common-sense method of treatment. The cerebro-spinal fluid, as already stated, is under high pressure, and contains an excessive amount of urea and of chlorides. Removal of fluid is often good for the headache of chronic renal disease, and I therefore find it hard to believe that relief of tension will not be beneficial in acute renal disease accompanied by nervous phenomena.

The giving of saline injections intravenously, subcutaneously, or into the colon in uraemia is of doubtful value. For a couple of years I employed Fischer's solution both intravenously and by the rectum, but could never satisfy myself that it was of value, and the rectal injection of the highly alkaline solution which he recommends, containing as it does 10 grams of sodium carbonate per litre, is extremely irritating. The injection of plain sodium chloride and of sodium citrate solution can be justified only as a diluent of retained toxins, and may be useful in this way, even though it is realized that the kidney finds difficulty in excreting both chloride and sodium ion. On the whole, I am inclined to recommend their use in the form of colonic injections after thorough evacuation of the colon.

As regards drugs, morphine, so long under suspicion in uraemic cases, is now recognized as both safe and satisfactory in checking repeated convulsions. It is hard to realize why this remedy was so long under suspicion, having regard to the fact that in the allied condition of eclampsia it has been employed for many years.

ACUTE NECROSIS OF THE PANCREAS*

BY

J. W. GEARY GRANT, F.R.C.S.,
Honorary Surgeon, Royal Infirmary, Cardiff

THE term "pancreatitis" as the subject of this discussion was deliberately chosen so that it might cover the wide range of conditions usually included under that heading, many of which are but little understood in order that those taking part in the discussion should not be tied down to any particular type, but might be able to give their views and experience of the many varieties of the condition, and especially of the less regular types or "formes frustes" of this somewhat rare disease.

In the few remarks that I have to offer, largely based on six cases of which I have had personal experience in the last two years, I propose to limit myself to the condition known as acute necrosis of the pancreas, which is a better term than acute haemorrhagic pancreatitis, as it does not beg the question of its primarily inflammatory origin, a view which is not held by a very considerable number of observers. Nor is the term "haemorrhagic" entirely satisfactory, as in a certain proportion of cases haemorrhage is not always strikingly in evidence.

THE PECULIAR FEATURES OF DISEASE OF THE PANCREAS

The pancreas has been well described as a laboratory of chemical physiology. In addition to its internal secretion, it forms the most powerful proteolytic ferment, the fat-splitting and the amylolytic, in addition to others of less importance. Another feature of this gland in which it differs from other secreting glands is that it possesses two ducts, sometimes in anastomosis, sometimes not, and of which, to use an Irishism, the lesser—the accessory duct of Santorini—is sometimes the greater. The latter duct has no valve at its entry into the duodenum, a fact the importance of which will be seen later. The main duct of Wirsung in the majority of cases joins the bile duct before it pours its contents into the duodenum, the distance of this junction from the intestinal opening varying from zero to 11 mm., averaging about 4 mm. All these facts have a bearing on the canalicular theory of pancreatic necrosis.

In the view of many writers on the subject the varying forms of acute pancreatitis as described in the textbooks are simply stages of the same process, and are described by Brocq¹ as acute oedematous pancreatitis, acute haemorrhagic pancreatitis, and gangrenous and suppurative pancreatitis, the rarity of the first being due to the fact that the surgeon seldom sees cases at this early stage.

As regards the suppurative varieties, probably some are primarily infective, whether the infection is due borne or by way of the lymphatics, but many are simply secondary infections following on the necrosis of the gland.

In studying the various papers and case reports of acute pancreatitis one cannot but be struck by the varying types of the disease which they describe, the great difference in the mortality of different clinics, the diverse views held as to its etiology, and in some degree also as to the appropriate treatment.

This is perhaps not to be greatly wondered at, when in a condition relatively uncommon, it can only fall to the lot of any individual surgeon to meet with a limited number of cases. Further, in many of the necropsy reports there is no account of a minute examination of the ducts which would throw some light on the etiology. In reading the papers of Deaver and other supporters of the theory of lymphatic extension from the gall bladder it would appear that, as is well put in a paper by Fiske Jones,² they are describing a condition different altogether from that of acute pancreatic necrosis, and that whilst that theory may well account for chronic pancreatitis and some of the suppurative varieties, it is not applicable, at any rate, to the majority of cases of the former condition.

ETIOLOGY

The immediate cause of the production of the *drame pancreatique* is the setting free of the secretion of the

* Read in opening a discussion in the Section of Surgery of the Annual Meeting of the British Medical Association, Cardiff, 1928.

pancreas and its activation in the ducts of the gland. In order that this may take place it is necessary first that the gland should be in the phase of secretion, secondly that the proferments should be activated by some agent or other. When these conditions are fulfilled we have all the factors required for the production of pancreatic necrosis. On the extent to which this takes place and the duration of the process depends the varying severity of the different types of the disease.

The importance of the first condition is shown by the experiments of Brocq, in which bile was injected up the duct of Wirsung, it being found that haemorrhagic necrosis resulted only in those cases in which the dog had received a full meal some hours previously. Clinically it is often noticed that the sudden onset of the disease occurs after a heavy meal.

The second condition, activation of the proferments, may be fulfilled in one of several ways. Brocq found that normal bile would do this if the first condition was fulfilled. Archibald found that bile deprived of its mucus, or in which the salts were concentrated, was efficient. Succus entericus, the normal activant, as might naturally be expected would also activate the secretion and might gain access to the gland through a patent duct of Santorini. In addition to these the products of the cytotoxicity of gland cells and leucocytes, calcium salts, and bacteria may have the same result. For those who hold the theory of Deaver of a lymphatic extension of inflammation from the gall-bladder and a primary inflammatory pancreatitis, these would furnish the activating agent and may give an explanation of some of those cases which are unassociated with disease of the biliary tract.

It is therefore probable that acute necrosis may be produced in more than one way. At the present time there are three main theories of its causation.

1. That it is due to a vascular lesion—embolism of pancreatic arteries or thrombosis of pancreatic veins.

This theory, defended by Gilbert, Chahrol, and Lapine has probably few adherents, and little can be advanced in its support. That in certain cases thrombosis of pancreatic veins may be found *post mortem* is what might well be expected with a sloughing or suppurating mass of tissue. As regards an arterial origin, with the rich vascular supply and anastomosis of the pancreatic arteries, this does not appear a very likely cause (Brocq). Experiments on dogs in which arteries have been blocked by inert powder injected into the arteries have failed to produce the lesions of pancreatic necrosis.

2. The infective theory, strongly upheld by Deaver and Mangeret, and lately supported by Gilman, Judd, and Mann, of infection spreading by way of the lymphatics from the gall bladder to the head of the pancreas, to what Deaver terms the triangle of infection.

Against this theory it may be said that in the vast majority of instances the haemorrhagic fluid in the general abdominal cavity and in the lesser sac is sterile. Kaufmann, in a series of experiments on cats, in whom he infected the liver with staphylococci and traced the infection to the gall bladder and through the lymphatics of the common duct to the pancreatic lymph gland, found no lesions in the pancreas resembling acute necrosis.

As infections of the gall-bladder, accompanied or not by calculi, are common enough, it is difficult to see why this spread of infection and its resulting acute pancreatitis does not occur more frequently. Again, it is by no means uncommon to find posterior ulcers of the stomach perforating on to the pancreas, which in some cases actually forms the floor of the ulcer, but in a series of 340 cases of acute pancreatitis collected by Brocq in only 2 was a gastric ulcer, and in 3 a duodenal ulcer, mentioned as a possible cause of the condition, and yet one would imagine that this would furnish a ready means of conveying infection to the pancreas.

3. The theory that necrosis is caused by regurgitation of bile up the pancreatic ducts.

Since the classical work of Opie this view has been held by many, and the investigations of Brocq and Binct and of Archibald have greatly strengthened it. The pancreas is protected from self-digestion by several safeguards. The proteolytic ferment is inactive in the gland

in the state of protrypsin, and remains so normally until it encounters the enterokinase of the succus entericus in the duodenum. Of the condition of the lipase less is known, but it is known that it bile is not necessary to activate the lipolytic ferment to very greatly increase its action in splitting fats.

In experiments by Brocq and Binct it was found that when the duct of Wirsung in the dog was divided and left open in the peritoneal cavity fat necrosis did not ensue, but if at the same time the gall bladder was opened and the bile and pancreatic secretion were allowed to mix, haemorrhage and stent necrosis followed. Further, whilst the injection of normal bile into the ducts of a fasting dog had no apparent effects on the gland when injected after a full meal the typical appearances of acute haemorrhagic necrosis followed in due course. It was further found that the active agent was the glycocholate of soda, whilst the taurocholate and the pigment gave a negative result.

As regards the mechanism by which bile may gain access to the gland, there is that first described by Opie, where a small calculus was found impacted at the bile papilla, the bile duct and the duct of Wirsung thus being thrown into a common channel. A considerable number of such cases have been reported, and many more have probably escaped observation, the stone having either passed on during the course of the illness or having been dislodged in the manipulations of the necropsy. Incidentally it is worth noting that in quite a number of reports it is stated that the stones in the gall bladder were very small, this being so in 4 out of 6 of my own cases, where the stones were of such a size that they would be competent to block the opening at the bile papilla without at the same time blocking the duct of Wirsung. This can only occur in cases where the length of the ampulla is at least twice the diameter of its opening into the duodenum. Such a condition, it is said by Judd and Mann, can only occur in 9 of 200 individuals but Opie found in 100 cases at necropsy that it could take place in 30 out of 100. Even taking the former view as correct, in a comparatively rare disease 9 in 200 possible persons would not be an argument against this method of production. Spasm of the sphincter of Oddi has also been invoked as a means by which the two channels can be thrown into one. Against this it has been said that this sphincter also encircles the duct of Wirsung and so would tend to close it. As regards the low pressure of bile in the ducts, Judd and Mann found that vomiting would raise the intraductal pressure to 1,000 mm. of bile.

There are other ways by which the secretion in the ducts of the pancreas can be activated, and the normal activant is the succus entericus. In 10 of 100 individuals Opie found the duct of Santorini larger than, or equal in size to, the duct of Wirsung. The opening of this duct has no valve, violent vomiting would therefore be competent to force duodenal contents into the substance of the pancreas.

Archibald, in his experiments on cats, in which animals the duct of Wirsung joins the common duct as in man, used (1) infected bile, (2) human bile sterilized and deprived of its mucus, (3) solutions of bile salts. Spasm of the sphincter of Oddi was produced by the application of hydrochloric acid to the bile papilla after opening the duodenum, and the fluid was injected into the gall-bladder at graduated pressures. Infected bile in one instance, caused death in an hour, but whether this was due to a definite pancreatic lesion is doubtful. With the second two substances where the animals died or were killed at varying periods, he found cytotoxic necrosis of masses of secreting cells. In those animals which survived and were later killed it appeared that the necrotic foci were in process of absorption and repair by formation of fibrous tissue. He points out that it is probable that bile may enter the pancreatic ducts in some cases without doing harm, in others that focal necrosis may occur as the result of cytotoxic but without activation of the ferments and autolysis, and that many cases probably occur of mild attacks of pancreatitis which are undiagnosed and go on to the condition of chronic pancreatitis.

The conclusions he draws from these experiments are that infected bile enters the pancreatic duct owing to spasm of the sphincter of Oddi, such spasm resulting from

passage of gall-stones, a duodenal ulcer, etc., with or without increase of pressure in the biliary system, caused by vomiting.

As an inference from this he considers that the correct treatment of the condition is to decompress this system, and suggests that this may be effected by transduodenal exposure and division of the sphincter of Oddi, pointing out that cases of impacted stone in the ampulla in which this operation is performed usually do well. It is doubtful if a patient suffering from acute pancreatitis would stand such a heroic and time-consuming procedure, and if the immediate result would be more readily obtained by cholecystostomy or choledochus drainage. If, later, division of the sphincter seemed desirable, it conceivably might be done from within by an instrument on the lines of a urethrotome.

As regards his view that the retrojection of bile is due to spasm of the sphincter, it appears highly probable that this is the cause in a certain proportion of cases. The sphincter may embrace the common duct distal to the junction of the duct of Wirsung, in which case spasm would throw the ducts into a common channel. In others, fibres of the sphincter also surround the duct of Wirsung, and spasm would close both ducts and prevent the retrojection of bile (Judd⁴). Judd states that the former arrangement only holds in 4.5 per cent of bodies examined, but as Moynihan⁵ says, "Is it not possible, indeed probable, that they are present in a large proportion of those patients who suffer from acute pancreatitis?"

The tone of the sphincter is 100 mm. of water, but when thrown into spasm can resist probably 600 mm. (Judd¹¹). The maximum secretory pressure of the bile is 300 mm., but vomiting will raise the pressure in the ducts to 1,000 mm. It is known that after removal of the gall-bladder the extrahepatic ducts first dilate, and that only subsequently does the sphincter become incompetent. Is it not possible that some cases of acute pancreatitis which have followed on a cholecystectomy are due to the resulting spasm of the sphincter of Oddi and the rise of pressure in the common duct, especially in cases where there has been previous damage to the pancreas?

Among the rare causes of pancreatitis, one of some interest, and of which 50 instances have been collected from the literature, is that of the entry of an ascaris into the common duct and thence into the duct of Wirsung. The ascaris itself is not digested because it contains an antitrypsin, but it carries into the duct some of the duodenal contents. The factors of trauma and activation are here both present. An interesting picture of the worm lying in the duct of Wirsung, and the resulting pancreatic necrosis, is shown in a paper by Schmieden and Sebenius.⁶ In this same paper, based on a series of 2,137 cases of pancreatitis during the past eight years, obtained by a questionnaire addressed to 100 clinics, a list is given of 145 cases which followed on various abdominal operations. These cases consisted of acute pancreatitis, purulent pancreatitis, abscess, and fistula.

As the operative procedures that they followed are very suggestive and of importance to the surgeon, I may briefly mention some of those given by these authors. Especially to be noted is burying the duodenal stump in the pancreas, or damage to the duct of Santorini by sutures in the same procedure after gastrectomy, or in mobilizing the duodenum or resecting a duodenal ulcer, including the tail of the pancreas in the ligature of the splenic vessels in splenectomy or of the kidney pedicle in nephrectomy, pushing up a calculus impacted in the ampulla, and the retrograde passage of a sound in transduodenal choledochotomy. They also state that although a piece of pancreas may be excised with impunity in 99 per cent of cases, in the hundredth it may be followed by pancreatitis. It is interesting to note that they suggest that leakage at the suture line in gastrectomy after technically perfect suturing may be due to unrecognized injury to the pancreas and digestion of the catgut. In a case of gall-stones with cholangitis in which I washed out the duct with saline, although at operation there was no trace of pancreatitis the patient died two or three days later, and at necropsy a purulent pancreatitis was found.

That pancreatitis may arise from a chemical substance in the blood stream is shown by a fatal case after cholecystography, although another explanation is that the bile containing the concentrated dye reached the pancreas by way of the ducts.¹²

DIAGNOSIS

Regarding the pre-operative diagnosis, that this appears to have been correct in a restricted number of cases is due, in the words of Korte, to two reasons: first, that one does not always bear in mind that a sick person possesses a pancreas, although lesions of the gland are more common than is generally supposed, secondly, its symptoms are easily confounded with other more common acute abdominal conditions, acute intestinal obstruction, and the various conditions of the gall-bladder which so often precede or accompany the attack of pancreatitis. But I think it is rather that the idea of pancreatitis is so associated with the fulminating variety, the symptoms of which are well known and where the failure to diagnose is less likely to occur. It is in the "formes frustes" of pancreatic necrosis that the real difficulty arises.

During the past two years I have had six cases of pancreatic necrosis under my observation. Two of these I may briefly refer to as illustrating this difficulty.

One an unmarried woman, aged 32 was brought to hospital as an emergency case and was sent home. She was admitted a week later on my receiving day. I then saw her, diagnosed gall stones, and she was put on the list for my next operating day, as her condition appeared in no wise urgent. When the abdomen was opened a gangrenous gall bladder was found with two families of gall-stones, one moderately large, one very small. There was extensive fat necrosis in the omentum and mesentery. The gall bladder was removed and the abdomen drained. Three days later a large abscess formed and was opened up. At necropsy a week later the pancreas was found almost totally necrotic.

The following case illustrates the fact that the condition may be missed at operation.

A man, aged 55, who had had an attack of biliary colic a year previously, was suddenly seized with severe abdominal pain and became jaundiced. When the abdomen was opened the gall bladder full of stones was found to be perforated, the perforation being sealed off by omentum. There was some blood in the upper abdomen which was thought to have come from a vessel in the omentum. There was no fat necrosis and the pancreas was not exposed. The gall bladder was removed. A few days later the wound opened up and an abscess burst the entire pancreas forming a black slough lying in the abscess cavity.

These and other cases have made me feel that the current teaching that acute conditions of the gall bladder, empyema, etc., should be allowed to settle down and be operated on *à froid* is entirely wrong. In my opinion they are almost equally urgent with the acute appendix. Further, that where there is the slightest suspicion of the condition of the pancreas, it should be exposed to direct vision through the gastrocolic omentum.

Regarding laboratory methods of diagnosis, these are seldom available, the diastatic index, obtaining pancreatic secretion by the duodenal tube, and the estimation of blood sugar might be carried out in the less acute cases, while Loewi's test is readily performed, and if positive might help to confirm the diagnosis, although in one case it misled me.

A woman, aged 70 was admitted as a case of acute abdomen with an indefinite previous history. She had a sudden attack of generalized abdominal pain, moderate rigidity, and tenderness most marked in the epigastrium and left costo-vertebral angle. Adrenaline in the right conjunctiva gave a most marked dilation of the pupil. The abdomen was full of sero-purulent fluid, which was found at the necropsy to be due to peritonitis following on carcinoma of the bladder.

TREATMENT

In respect to treatment, the case records of various clinics differ. In some cases abdominal drainage of the region of the pancreas only, in others incision of the gland, ganze tamponage, and drainage, have given good results. In others, drainage of the biliary tract through the gall bladder or common duct is added, and it is difficult to see which has given the best results.

It appears certain that under no conditions should the gall-bladder be removed, and I should say that even a gangrenous gall bladder should be simply drained.

Two drugs, aspirin and hexamine, are secreted by the pancreas, and their administration theoretically might be

supposed to have some action in disinfecting the gland, and could at least do no harm.

Ohno and Schonback have immunized animals to trypsin, and have suggested immunization by an antitryptic serum, but I do not know if this has ever been carried out on human beings. The administration of nitrogen might be worth a trial on account of its inhibiting action on pancreatic secretion.

It is not impossible that some of the milder cases of this condition recover without operation, since pancreatic cysts may take their origin in a limited necrosis of the gland and escape of small quantities of secretion.

The indications as regards operative treatment are, in my opinion, to expose the pancreas through the gastrocolic omentum, to incise the peritoneum over it, and to place rubber drains to the swollen area and gauge tampons around to wall off the peritoneum and prevent the diffusion of the escaping secretion. It appears that more harm than good may be done by incising the pancreas itself, which might divide ducts and set free more ferments. If the gall-bladder was distended I should do a cholecystotomy, and if the common bile duct appeared distended I would drain this. Neither of these procedures should take much time or involve much disturbance of the parts or increase the shock. The result would then depend on the extent of the original damage to the pancreas.

THE CONTROL OF SMALL-POX.

BY

L. W. RATCHMAN, M.D.,

Director of the Health Organization League of Nations.

The manifestations of small pox in recent years have been characterized by (1) a very marked decrease in incidence, and (2) an almost universal decrease of the case mortality rate.

The case mortality rate has decreased partly through (a) the spread of alastrim, or a very mild type of small-pox, which seems quite unaffected by the trend of the ordinary small-pox, and partly through (b) a more favourable course of ordinary small-pox cases in many countries. It must be added that important outbreaks of severe small-pox have not ceased to occur, a fact of which we are reminded by the Rio de Janeiro outbreak in 1926, and that of Algeria in 1926-27.

In regard to the decrease of incidence in Europe it should be emphasized that this is not the first time it has fallen to a very low level, and also that the decrease is not universal. Though there were only 652 small-pox cases in Europe in 1927, outside the United Kingdom, the Iberian Peninsula, and Russia, 280,000 cases were notified that year in the whole world. If we add China and parts of Africa and South America, where cases are not reported, the total number of cases must certainly have largely exceeded 300,000. In India alone small-pox causes 50,000 deaths in an average year.

It must be borne in mind that small-pox is of a more truly epidemic character, in its year-to-year movements, than most other diseases. It attains a high incidence for some years, and falls then to a very low level. It is only

The opening paper in a discussion in the Section of Preventive Medicine of the Annual Meeting of the British Medical Association, Cardiff 1928.

in India that small-pox appears to be endemic at a constant level, but the size of the country accounts for this seemingly paradoxical phenomenon.

Even in the twentieth century very marked fluctuations in the incidence have been noted. A first epidemic wave occurred during the years 1901 to 1903. In England, London and the neighbouring counties were chiefly affected in 1901 and 1902, Lancashire and the northern counties, in which the mild small-pox was later to become prevalent, were affected during the following two years. Small-pox caused more than 4,000 deaths in England in these four years, when the classical type of the disease prevailed.

In other European countries it was no better, in Belgium there were 2,938 deaths from small-pox during the three years 1902 to 1904, with a maximum in 1903, in French towns of over 5,000 inhabitants, 4,903 deaths from small-pox were reported in 1902 and 1903. In Italy small-pox was epidemic from 1901 to 1904, during which years it accounted for 14,951 deaths.

Further east in Europe the wave had come a few years earlier, in Austria and Hungary its maximum occurred between 1897 and 1899, in Rumania in 1896 and 1897, and in Russia in 1898 and 1899.

Although a high endemic level persisted in Russia, Spain, Italy, and, probably, in the Balkans, with the exception of Rumania (maximum in 1906, 1909, and 1913), there were no further serious outbreaks in England and in northern and central Europe until 1920. In Italy there were new outbreaks in 1911 and 1912, 8,164 deaths having been attributed to small-pox.

Small-pox of severe type was widespread from 1901 to 1903 also in the United States, 3,578 deaths were reported during those three years in the registration area, which then only included about one-third of the country. The incidence fell subsequently, and from 1906 to 1909 it was as low as, or lower than, it had ever been.

Small-pox was widely prevalent in Japan in 1892, 1893, and in 1897—the same years as there were extensive epidemics in eastern Europe. During the first-mentioned two years 22,261 deaths were ascribed to small-pox, and in 1897, 12,276. Its incidence subsequently fell, and in each of the years between 1900 and 1903 only from four to seven deaths from small-pox were reported, indicating a much more favourable situation than in any of the years subsequent to 1915. There was a new epidemic in 1908, which caused 5,838 deaths. The incidence of small-pox increased again in 1917, and, although it has decreased considerably in recent years, there were still 92 deaths from small-pox in 1927.

We have to wait for the years of the war to witness a renewed increase of small-pox in southern, eastern, and central Europe. In the United Kingdom, the Netherlands, France, and northern Europe there was no increase, in Germany it was moderate, 448 deaths being ascribed to small-pox in 1917, and 704 in 1919. In Austria (pre-war territory) there were, on the other hand, about 50,000 cases in 1915 and 1916.

In Italy the incidence was low during the war, and reached a minimum with only 16 deaths in 1916, but in 1919 and 1920 there were severe epidemics causing 27,417 deaths. It is interesting to note that this epidemic occurred almost exclusively in southern Italy, which was the case also with the outbreak of 1901 to 1904. The provinces particularly visited on both occasions were Apulia with Basilicata, Campania, and Sicily.

The crest of this wave of small-pox which affected mostly eastern, southern, and central Europe, was in most countries reached in 1919. The incidence was still very high in 1920, but after that there was a general decrease, which has continued ever since. In certain countries the fall has been quite exceptional. Thus, in Rumania, where there were 20,523 cases in 1919, only 2 cases were reported in 1927. In Italy there were 34,363 cases in 1919, and only 69 in 1927. The number of cases reported in the Ukraine decreased from 34,730 in 1920 to 189 in 1927.

In 1927 fifteen European countries were altogether free from small-pox, while seven reported less than five cases each, in only eight countries were more than five cases reported. Exceptions to this general decrease have been extremely few. Besides England and Wales, where a mild form of small-pox began to spread in 1922, and Switzerland, where a similar mild type of small-pox was prevalent from

1921 to 1926 but has now entirely disappeared, only the returns for Franco show no decrease

In France the number of small-pox cases fluctuated during the last nine years between a minimum of 172 in 1922 and a maximum of 572 in 1919, with 554 in 1926. It may be added that, in contrast to England and Switzerland, the severe type is prevalent here. The incidence of small-pox in France decreased markedly, however, during the early months of 1928. For Portugal returns are not available until the second half of 1927, when 1,169 cases were reported, with 140 deaths. This, however, is considerably less than in the years immediately after the war, in 1919 small-pox caused 8,864 deaths.

Fig 1—Small pox cases reported in Europe, 1920-27. (x) Without Greece, Portugal, Spain, Switzerland and U.S.S.R.

The numbers of small-pox cases reported in European countries between 1919 and 1927 are shown in the accompanying graph (see Fig 1). It is noteworthy that the cases, if exception be made of the epidemic of mild small-pox in northern England and that of classical type in Algeria, have occurred entirely sporadically. An investigation of these cases, carried out at the request of the Health Organization of the League of Nations by the sanitary administrations of the various countries, has proved that, with the exception of France, where at least a part of the infection seems to be traced back to Algeria, no connexion between the various cases has generally been apparent. This is particularly noteworthy in regard to the few cases that have occurred in central Europe and the Balkans.

The case mortality of small-pox varies greatly, not only from one country to another, but also from year to year.

Fig 2—Small pox case rate and death rate per 100,000 in habitants and case mortality rate per cent. in Italy, 1888-1927.

Italian statistics are very instructive in this regard. Reports, which are undoubtedly reasonably complete, are available both in regard to cases and deaths since 1888, and the number of cases and deaths have in every year been sufficiently high to establish a significant case mortality rate.

It is seen from these returns that the case mortality rate has moved in waves, generally corresponding to those described by the incidence, but even more regular in character. The accompanying diagram (Fig 2) shows, for

example, that the maxima of case mortality occurred in Italy in 1889, 1893 to 1894, 1903, 1911 to 1912, and 1919, the movement of this rate was entirely regular during the intervening years, the minima being reached in 1892, 1899, 1906, 1915 to 1916, and 1923. It would seem that a cycle of seven or eight years existed in the height of the case mortality rate.

The minima have gradually become lower, that of 1892 being 15.8 per cent, that of 1899, 7.2 per cent, that of 1906, 6.8 per cent, that of 1916, 2.5 per cent, and that of 1923, 3.2 per cent. The maxima were 33.8 per cent in 1889, 38.5 per cent in 1895, 31 per cent in 1903, 25.3 per cent in 1912, 47.7 per cent in 1919, and 41.7 per cent in 1920.

Two explanations of this phenomenon are possible: (1) the fluctuation in the degree of severity of classical small-pox, and (2) that classical small-pox might tend to disappear in certain periods, and be replaced by the milder forms. The second explanation is unlikely, however, so far as Italy is concerned, as the minima of the case mortality rate have mostly been reached in years when small-pox is relatively rare. There is no reason to believe that changes in vaccinal conditions could produce such periodical changes in the case mortality rate. Statistics of deaths are not, as yet, available for 1926 and 1927, but a special report prepared by the Italian Health Service states that the type of small-pox prevailing during these two last years has not been very severe, and the fatal cases have been rare.

Japanese statistics for the years 1881 to 1927 also show marked fluctuations of the case mortality rate. These

Fig 3—Small pox cases reported in England and Wales, by four weekly periods, 1922-27.

fluctuations have been less regular than those observed in Italy, but this may partly be due to the fact that the number of cases in Japan during several periods, notably from 1900 to 1906, and from 1909 to 1916, has been very low, and chance fluctuations of the rate have to be taken into account. Clearly defined maxima, however, have occurred in connexion with the epidemic outbreaks of 1886, 1893, 1897, and 1908. On the latter two occasions an increase of the case mortality rate to a maximum occurred in a year preceding the epidemic. The case mortality rate fell markedly from 1919 to 1926, but in 1927 it increased again, and it is obvious that the average rate is not lower now than it was forty or fifty years ago. It is evident that the fall of the case mortality rate which occurred after 1920 in England and Wales is not of the same nature as the fluctuations which we have just shown for Italy and Japan.

The case mortality rate was 11.4 in 1920 in England and Wales, it fell during the following year to 1.6, and to 2.8 in 1922, after which it decreased to 0.3, it has remained between 0.2 and 0.3 ever since. The figure of 2.8 for 1922 is really misleading. It is due to an outbreak of classical small-pox in the London area, comprising 78 cases with 24 deaths, giving a case mortality rate of 31 per cent. There were thus in the remainder of the country 895 cases with only three deaths, giving the case mortality rate of 0.3 as in the following years.

The mild type of small-pox is said to have made its appearance in England in 1919. It was evidently not until a few years later that it entirely overshadowed the isolated outbreaks of classical type and it is clear that from that moment the case mortality rate fluctuated around a level different from that of former times. (See Fig 3)

The statistics for the United States Registration Area for deaths show that the fall in the case mortality rate preceded that of England. While, up to the end of the nineteenth century, the case mortality is known to have been about 20 per cent in the States belonging at the time to the registration area, it had already fallen to between 3 and 4 per cent during the first five years of the twentieth century. A sudden and decisive fall below 1 per cent was recorded in 1906, and it has remained at this level with a few sharp variations. When the case mortality rate rose above 1 per cent in 1910, 1922, 1924, 1925 and 1926, it was due to fairly isolated outbreaks of small pox of severe type, believed to have been imported from Mexico. The outbreaks in Detroit in 1924, in Minneapolis in 1925, and in Los Angeles in 1926 were of this type, and operated much in the manner of the 1822 London outbreak in swelling the general rate for the country as a whole.

In continental Europe the case mortality rate appears to have fluctuated on the level typical for classical small-pox, with the exception of Switzerland, where the mild type of the disease between 1921 and 1925 gave a figure of 0.2 per thousand cases, similar to that for England and Wales.

In Germany the rate varied between 12 per cent and 16 per cent during the years 1919 to 1922, when the disease was fairly widespread. From 1923 to 1927 only 68 cases were reported in Germany with 26 deaths, a rate of 39 per cent. For France the figures were between 28 and 29 per cent from 1919 to 1921, and 24.8 per cent in 1925. Statistics of deaths for the years 1922 to 1924 have not yet been published. In Portugal the figure was 12 per cent during the second half of 1927, although it had been considerably higher in previous years, in 1925 it was 34 per cent in Lisbon and Oporto. In Rumania the figure stood at 28.4 per cent during the severe epidemic of 1919, it decreased gradually as the incidence became lower, and was 12.4 in 1923. It has not fallen appreciably since, 5 deaths having been reported for the 46 cases notified during the last four years. In the kingdom of the Serbs, Croats, and Slovenes the figure was between 22.6 and 22.8 during the years 1920 to 1922, 19.1 in 1923, and 18.4 in 1924. No further increase has occurred, 5 deaths having been reported with the 21 cases notified in these last three years. The type of small pox prevailing in Greece is said to have become milder than formerly, 2,101 cases with 683 deaths were reported in 1923, giving a case mortality rate of 32 per cent. In 1927 there were 22 cases, with 3 deaths, reported as small pox, and 93 cases, without any deaths, reported as varioloid.

The figure in extra-European countries falls generally between 10 per cent and 30 per cent. In India it was between 24 per cent and 25 per cent in relation to the reported cases in 1926 and 1927. In Korea it was between 23 and 24 per cent during the same years.

Interesting fluctuations have occurred in Java, where the figure decreased from 25 per cent in 1912 to 12.1 per cent in 1917, rose again to 26 per cent in 1918, and gradually decreased to 12.3 per cent in 1923, to rise once more to 21.8 per cent in 1924. There has since been a decrease and it was only 2.7 per cent in 1927—an exceptionally low figure for a tropical country.

The reported rate in Egypt has usually fluctuated between 20 and 30 per cent, and has become lower during recent years, as it was 14.2 per cent in 1927. Statistics for various African colonies such as the Gold Coast, Nigeria and northern Rhodesia, show that small-pox epidemics with a fairly low case mortality rate (2 to 10 per cent) are not rare. There are, however, occasionally epidemics of a much more severe type having a case mortality rate of 30 per cent or more. For the southern part of Africa the rate is certainly influenced by Kafir-pox, which is distinctly of the benign type.

The general impression gained as to the case mortality rate actually obtaining in the various parts of the world is that two entirely distinct types prevail: (1) the classical type the rate of which is fluctuating in long waves generally between 10 per cent and 30 per cent, and (2) the mild type, with figures between 0.1 per cent and 0.3 per cent. The periods of minima presented by the classical

type do not appear, in any way, to be intermediate between that and the mild type.

Small-pox deaths have been too rare in recent years in most European countries to establish reliable death rates by age. Italian statistics for 1918 to 1921 show very marked excess in the female death rate at ages between 20 and 44 (see Fig. 4), the low incidence among males at this age may be explained by vaccinations during military service. At ages under 15 the difference in rate between boys and girls was very slight, at ages over 55 there was

FIG. 4.—Small pox death rate by sex per 100,000 population in Italy, 1918-21.

an excess of male mortality. These figures correspond to the rates for 1901 to 1905 except that the excess of female mortality as shown in 1918 to 1921 was not noticeable.

The age distribution of small pox deaths is greatly influenced by the racial condition obtaining in a given country, and it is difficult to determine whether fluctuations due to any other cause occur.

The seasonal distribution of mild small pox does not appear to differ materially from that of the severe type. Both have usually their maximum in winter or early spring, although one or two notable recent exceptions are on record.

THE SERUM CALCIUM IN EXPERIMENTAL TUBERCULOSIS*

BY

J. CLIFFORD HOYLE, M.B., B.S.
(From the Pharmacological Laboratory, Cambridge.)

TUBERCULOSIS has long been recognized to be associated with changes in calcium metabolism. For example a close relationship exists between arrest and calcification of lesions, and, apart from this, tuberculous tissues often contain many times the normal amount of calcium. Earlier observers held that a "demineralization" occurred during the disease, due to increased excretion of mineral elements. This has since been disproved repeatedly, and, so far as calcium is concerned, there is no sound evidence of any decreased retention during tuberculous infections, except possibly in the terminal stages.

During recent years reliable methods for estimating the serum calcium have been found, and a number of investigations in clinical tuberculosis have been published. Several workers found no changes,¹ but the balance of evidence shows that in active phthisis the serum calcium is lowered, and in arrested disease is raised on the average. No attempts have been made to explain the cause of these results whether the fall is associated solely with the tuberculous infection or is due in part to superimposed secondary infection remains doubtful. Some evidence strongly suggests that secondary and septic infections lower the serum calcium,² and I propose to offer further proof of this. Clinical observations on phthisis

* Read in the Section of Tuberculosis of the Annual Meeting of the British Medical Association, Cardiff, 1928.

cannot exclude the influence of secondary infections nor the effect of such infections on the tuberculous lesion, but this difficulty does not obtain in experimental animals.

The present paper deals with the changes in the serum calcium level found in rabbits during experimental bovine tuberculosis, using intraperitoneal and subcutaneous inoculations. In all experiments serum cultures fourteen days old were used for inoculation, and the dose given was estimated by the method used by Griffith in his work for the Royal Commission.⁴ Clark and Collip's modification⁵

FIG. 1.—The serum calcium and weight curves during experimental bovine tuberculosis in the rabbit (Rabbit 78). Intraperitoneal inoculation of 0.001 mg. bovine tubercle bacilli.

of the Kramer-Tisdall method⁶ was used for the analyses. The normal physiological range of the serum calcium in individual animals is about ± 5 per cent over a period of a few weeks.⁷ Taken over a longer time than this the range is greater, about ± 10 per cent, due to a seasonal factor.⁸

Intraperitoneal Inoculation

The rabbit has a low resistance to bovine tuberculosis. With intraperitoneal inoculations the disease becomes generalized, consisting of widespread miliary or submiliary lesions which show a varying extent of caseation. The animal dies in from a few days to a month or two, depending upon the dose of organisms and the individual susceptibility of the animal. The infection remains throughout a pure tuberculous infection. If the animal dies in less than thirty days, the serum calcium only falls in about a third of the experiments. Where no fall occurs the lesions show relatively little caseation, and in every case where the fall is considerable caseation is striking. Rabbit 78 (Fig. 1) shows this, and also the close correspondence between the serum calcium and weight curves. The normal serum calcium was 13.95 mg. per cent. Four days after inoculation of 0.001 mg. of bovine tubercle bacilli it remained steady at 13.99 mg., on the eleventh day it was 13.66 mg., on the eighteenth day 12.12 mg., and on the twenty-fifth day 10.35 mg. per cent. The animal was then killed and *post-mortem* examination showed generalized miliary disease, confluent in places, throughout the peritoneum. Both lungs were packed with caseating tubercles (tubercle bacilli +). Such experiments suggest that a determining factor in producing the fall in serum calcium is the degree of caseation in the lesion. It was mentioned above that caseous tissue has a high calcium content.⁹ Whether the drain upon the circulating calcium by progressive storage in the lesions is responsible for the fall in serum calcium remains to be decided.

When the animal survives longer, the course of the infection can be divided into three stages, according to the changes in the serum calcium. During the first three weeks of the disease it usually rises about 10 per cent, with a subsequent fall to a level of some 10 per cent below the pre-inoculation values. The total range during this time is thus some 20 per cent, or about twice the average variation in normal animals. During the fourth week a very constant rise in the serum calcium occurs of 10 to 20 per cent. Later, until the death of the animal,

there is usually a progressive fall, and very low values, such as 7 to 8 mg. per cent, may be found in the last week or so. No evidence for the cause of these changes can be offered at present. The fall in the third stage, however, may be due to progressive withdrawal of calcium to the lesions during caseation.

Subcutaneous Inoculation

With subcutaneous inoculation the disease is more chronic than with intraperitoneal. During the first three weeks a caseous lesion forms at the site of inoculation and the regional lymphatic glands become palpable. If the inoculation is superficial the local lesion ulcerates, leaving a discharging ulcer with undetermined edges and caseous floor. With the secondary infection the regional glands enlarge rapidly. Later, about the eighth to tenth week, the ulcer improves, and may almost heal before the animal dies from the generalized disease. Lesions in the lungs may be established as early as the third week after inoculation, and later are so extensive that normal lung tissue hardly exists.

It has been found that the serum calcium shows definite changes corresponding to these stages in the progress of the disease. These are shown diagrammatically in Fig. 2. While the local lesion is forming, but before it ulcerates, the serum calcium invariably rises to the upper limit of the physiological range, and in about half the cases exceeds this by 15 per cent. During this time there are no lesions in other organs of any significance. This shows that so long as a tuberculous infection remains purely local the serum calcium is well maintained, and if anything is rather above normal. Whether this rise is "compensatory" in response to the demand for calcium by the caseating local focus is not known.

Immediately the local lesion ulcerates the serum calcium begins to fall, and this continues until the ulcer shows improvement. The extent of the drop varies in individual animals from 16 to 37 per cent. In one experiment the low value of 9.3 mg. per cent was found. The fall is associated with, and probably due to, the presence of secondary infection. If the inoculation is given deeply

FIG. 2.—Diagram of the typical changes in the serum calcium of the rabbit following subcutaneous inoculation of bovine tubercle bacilli (black line). The shaded area represents the normal range and rises slightly owing to the influence of the seasonal factor at the time the experiments were performed.

and no ulceration of the local lesion occurs this fall is absent. Moreover, septic infections in normal rabbits—for example, on the ears—result in a comparable drop in the serum calcium. How secondary infection produces this fall is not known. It appears unlikely that it is due to loss of calcium in the discharge, as there is evidence to show that septic infections in which there is no discharge are associated with a similar fall in the serum calcium.¹⁰ Conceivably it might be due to endocrine dysfunction, but no evidence is available at present to substantiate this.

After about the tenth week, when the ulcer improves, the serum calcium returns to normal, usually in about three weeks. If the animals survive much longer, during the remaining weeks it continues normal or slightly higher. This is in striking contrast with the results obtained after intraperitoneal inoculation. In the latter experiments the pulmonary lesions were mainly sublobular in character. With subcutaneous inoculation they were always much more extensive, and the weight of the lungs, generally, was over 80 grams (normal 8 grams). They consisted entirely of solid caseous masses, and such extensive disease must inevitably interfere mechanically with pulmonary gas exchange, and give rise to alterations in the acid-base balance. Evidence exists to suggest that necrosis results in an increase in the serum calcium.¹¹ How far this may be operative during the later stages of my experiments, and thus mask the fall that might be expected, remains for further investigation.

THE MODERN TREATMENT OF VARICOSE VEINS

THE HISTORY OF ITS EVOLUTION.

BY

C. H. COLT, M.A., M.B., B.Ch. Cantab., F.R.C.S.,
SURGEON TO ABERDEEN ROYAL INFIRMARY AND LECTURER ON CLINICAL
SURGERY, UNIVERSITY OF ABERDEEN.

THE passing of the operative treatment of varicose veins may be regarded as a merciful release for the surgeon, but a tribute is due to those who made the modern operative treatment eminently effective in male, and on the whole fairly effective in female, subjects, and so led directly to the success of the injection treatment.

Briquet¹ in his famous thesis of 1824, showed that varices were most common where the deep veins communicate with the superficial, and many French surgeons at the time confirmed this fact. Callender,² in addition demonstrated that the united capacity of the communicating vessels was relatively very large. Verneui³ from twenty-one dissections concluded: (1) That whenever spontaneous superficial varices existed in the lower limb the corresponding deep veins (intra- or inter-muscular) were also varicose. (2) That the correlative position was not proved. (3) That phlebectasis in the lower limbs began in the deep veins in general. These vessels first dilated, the valves then became inefficient and the lesions extended to the second and third rank of subcutaneous veins. (4) That phlebectasis never began in the trunk of the internal saphenous, but in its secondary and anastomosing branches. (5) That deep varices were more common than subcutaneous varices. Specimens illustrating these points are found in the Musée Dupuytren. Gay,⁴ in an exhaustive review of the whole subject showed that ulceration was not a direct consequence of varicosity alone, but of incompetence of the circulation as a whole. He noticed that in many cases the blood disappeared from the veins of the leg, but not from those of the thigh on elevating the limb. From his injection experiments on the cadaver he concluded that tegumentary (veno-capillary) injection denoted obstruction of the femoral

vein, and began round the patella, while subtegmentary (venous) injection denoted obstruction of the sphenous. The intramuscular veins were not found to be injected in the experiments, and appeared to be difficult to inject.

THE PHYSIOLOGY OF TREATMENT

Trendelenburg's Sign

Sir Benjamin Brodie,⁵ at least fifty-four years before Trendelenburg's⁶ publication, gave a lucid description of the patient with Trendelenburg's sign. He said:

If the veins are but little dilated or dilated only in particular places the valves will still continue to answer the purpose for which they were designed. If the vena saphena be not at all dilated, while the smaller veins of the leg are dilated the valves of the vena saphena not perfectly and take off the weight of the column of blood pressing on the veins below. But if the vena saphena be itself considerably dilated, its valves of course are rendered inefficient. Now observe the result of this. I had a patient in whom there was an unusually large cluster of varicose veins on the inside of the leg while the vena saphena major was of enormous diameter so that the valves were evidently good for nothing. If I put on a bandage and squeezed the blood out of the veins below, and then put my thumb on the vena saphena above, so as to stop the circulation through it I found on taking off the bandage, the patient being in the erect posture that the cluster of veins below filled very slowly and only from the capillary vessels. But if the patient being in the erect posture I removed the pressure from the vein the valves being of no use the blood rushed downwards by its own weight contrary to the course of the circulation and filled the varicose cluster below almost instantaneously.

Jennel,⁷ in his masterly summarizing of the whole of this part of the subject in 1910, stated that no one clearly comprehended the importance of valvular insufficiency or its consequences and operative indications until the publications of Sobolev (1889)⁸ and Trendelenburg (1890)⁹ which gave us the conceptions of the passive or superficial reflux (abdominal or superior of Delore),¹⁰ and of the active or deep reflux (inferior or muscular) from the deep veins of the leg towards the superficial veins. V. Meisen¹¹ finds the venous pressure in the valveless saphena to range from 25 cm. of water in the thigh to 80 cm. in the leg just below the knee, and to be increased by static muscular action.

THE MODERN OPERATION

Coming as it did at the time when complete sphenectomy was being made easy by the new anæsthetic methods, Jennel's summary was helpful to surgeons everywhere. Keller¹² in 1905 published the first inside-out extraction method, and Mayo¹³ in 1906 the enucleation method. Birkbeck¹⁴ in 1907 introduced an important modification by means of which the vein is not turned inside out, but is removed in a bunched-up state on one end of the wire. This method, with certain modifications by Sir Henry Gray¹⁵ in 1909, being more certain than inside-out avulsion became the operation of choice in the great majority of cases. O'Sullivan¹⁶ and Mannuram¹⁷ were early advocates of the method in England. Combined with ligation and ligature of the remote ends of the tributaries especially at their junction with the deep veins and with the external saphena system, the whole of the internal saphena system is put out of action with ease and rapidity, thus greatly simplifying and shortening what is otherwise a very tedious procedure, and one involving absurdly long incisions. The trunk of the internal saphena is seldom very tortuous, whereas the tributaries are so that the efficiency of the method is very great, and the results, in males at any rate, are distinctly good. Thus for example, out of 22 cases¹⁸ operated on in the Aberdeen Royal Infirmary by this method since the war, and in which it has been possible to trace the patients, the results are as follows. In 9 male cases traced up to six years after operation, 6 results are very good and 3 are good whereas in 13 female cases traced up to four years, only 3 results are very good 6 good, and 4 moderate or bad, 7 of the female patients have since had further treatment by injection. The differences in the results seem to be due to three chief factors: (1) Pregnancy and the harder forms of work in the female. (2) The greater degree of fatness, so that the tributaries are not well seen before operation. (3) Postponement of operation. (The question of hyperthyroidism

* A post-graduate lecture delivered at Aberdeen University during the summer term 1928.

For some of this material I am indebted to Professor Sir John Macninch K.C.V.O. under whose care the patients were treated when I was his assistant surgeon.

is omitted here) One of the chief factors in this type of operation is its early performance before the superficial reflux has caused extensive disease in the smaller veins. Thus the soldier patient comes under treatment early as a rule. In five such patients traced thirteen years after operation it is apparent that a good result at the five-year period is likely to be permanent. On the whole, the trial of the method which was begun in August, 1914, has fully justified the work of the older surgeons. In the 94 consecutive cases, representing 149 limbs and involving the extraction of about 112 yards of vein, there has been no mortality, no pulmonary embolism, no infection, and little suppuration, but a fatal case of embolism is recalled before 1914, in which a venous cyst in the groin was excised in a female patient who had been in bed for a fortnight after an operation for femoral hernia on the opposite side. Both wounds had healed by first intention. There was no *post-mortem* examination. It is very remarkable that embolism is so rare in an operation in which large numbers of deep communicating venous channels are broken across and left open. Before 1914, also, one case of extensive varix in a male treated by Balcock's method and local excision turned out a complete and absolute failure, due apparently to a duplication of the internal saphena and perhaps other veins. Many authors mention this duplication, but we do not know the frequency of its occurrence or whether it has any bearing on the causation of varicose veins. It has been present at least three times in the last 37 cases operated upon.

TREATMENT BY INTRAVENOUS INJECTION

The injection treatment* may be said to date from the invention of the Pravaz syringe in 1851.²⁰ Septic phlebitis, sloughing, septicæmia, and embolism frequently followed the earlier injections of iron perchloride. Socquet in 1854 discovered the iodotannic solution, which Desgranges²¹ and Barrier adopted, and reported six successful cases without accident. Large hard clots formed in twenty-four hours with considerable pain, and took several months to disappear. The patients had to lie up, and relapse sometimes occurred owing to the clot dissolving in the alkaline plasma. In 1876 began the era of perivenous injections for the cure of varicose veins and ulcer, varicocele, hæmorrhoids, and rectal prolapse by the injection of solutions of ergot, alcohol, iron perchloride, chloral, or carbolic acid, notably by English at Vienna in 1875 with 5 per cent alcohol. Trouble arose from sloughing, scarring, and recurrence, but there were many successful cases. Delcroix²² in 1894 defended the intravenous iodotannic method, and showed that its efficiency depended on the chemical endophlebitis set up with the thickening of the wall of the vein. Tavel of Bern²³ in 1904 tied the saphenous vein and injected 5 per cent carbolic acid below the ligature. Schiassi of Bologna²⁴ in 1903 similarly injected 30 to 50 c cm of 1 per cent iodine in a 1 per cent potassium iodide solution, and resected the part of the vein where the cannula had been. About this time Zirn²⁵ was trying mercurial preparations with success, 1 to 2 c cm of a 1 per cent solution of sublimate being injected into the internal saphenous vein above the knee. Borchers²⁶ in 1910 injected 300 c cm of salvarsan into a varicose vein with the patient recumbent. Three days later the vein was not to be seen, and the patient has remained well ever since. He has obtained the same effect with galyol, kharsivan, neo-kharsivan, and novarsenobillon. Scharff²⁷ in 1912 used weak perchloride solutions. Hanschell²⁸ noticed the cure of a varicose vein in 1913, after the injection of 10 grains of quinine in 10 c cm of water. There was thrombosis and periphlebitis, he noticed the same effects with salvarsan. In 1916-17 Professor Sicard²⁹ observed obliteration of the veins following numerous intravenous injections of luargol in which there was free soda, and in March, 1918, began to inject varices with neutral sodium carbonate in doses of from 5 c cm of 5 per cent solution to 15 c cm of 15 per cent solution, publishing his results in 1920. On account of the scarring which may follow escape of the soda into the subcutaneous tissues, a solution of sodium salicylate in strengths of 20 to 40 per cent was later adopted.

* Bazelin³⁰ in his thesis gives an admirable summary of the whole of this subject up to 1924.

Genévrier and Cibrion³¹ employed a 13 per cent solution of neutral quinaao hydrochloride with 6 per cent urethane as an analgesic. Other solutions tried with success are sodium citrate 100 per cent, sodium chloride 20 per cent (Luser³²), 50 and 66 per cent grapo sugar (Nobl³³)—the last in 2,960 cases after having used sublimate 1 per cent with success in numerous others. The chief objection to the mercurial preparations is their toxicity, we must also remember that quinine sometimes produces blindness³⁴, the risk is said to be about 1 in 1,600.

CLINICAL PATHOLOGY OF THE INJECTION METHOD

There seems to be a general agreement among those who have examined the veins after injection with various solutions that for about the first hour there is no naked-eye change in the endothelium. The vein contracts, and the walls may stick together, giving a splendid result surgically. With some solutions sudden clotting occurs, resulting later in a thick fibrous cord, which takes months to disappear. Gradual thrombosis allows the excess of blood to be slowly removed, and this, surgically speaking, is greatly to be preferred. In twenty-four hours the endothelium is tumefied, and there may or may not be infiltration and peripheral clot. The clot, when formed, is always firmly adherent from the start. In one of V Meisen's cases it was not separated by strong massage, which is comparable with the degree of molecular adhesion found between an aseptic clot and a piece of dull-gilt wire inserted into an aneurysm. The clot in this case in the recent state has actually to be scraped off the wire. In forty-eight hours the vein is still contracted, the endothelium swollen and covered with fibrous deposits. In seventy-two hours the endothelium is proliferating strongly. In a week the clot is undergoing organization and the lumen of the vein is greatly narrowed. At this stage one can gauge fairly accurately the most suitable site for the next injection. In a fortnight the clot is well organized. Later it does not soften or degenerate, but becomes a firm fibrous cord. Sir Sidney Alexander³⁵ suggests that the term "chemosis of the intima" would be better than "endoventitis." The vein may die, the tissues around it may necrose. Both remain aseptic if protected from infection, the dead tissue forming a scab which separates in about six weeks and leaves a slowly healing ulcer, or healing may take place under the scab.

VARIATIONS IN THE EFFECTS

Douthwaite³⁶ states that thrombosis produced by the quinine solution does not spread rapidly, as it may do with the salicylate solution, and that the risk of persistent ulceration from faulty injection is less. Hanschell's²⁸ experience differs from this, and Hopworth³⁰ noticed phlebitis extending downwards from the site of injection. Sometimes the walls of the vein adhere at once with immediate and permanent obliteration of the channel, sometimes there is an extensive reaction in both directions from the site of puncture, sometimes no reaction occurs at all, and yet on repeating the injection a week later in the same way a marked reaction occurs. There is therefore little doubt that the chief variables—namely, the blood volume and the blood current at the site of injection—have a great effect. We know that in a horizontal varicose vein the blood may be moving slowly in either direction, or that it may be stagnant. In the vertical position, or even raised 45 degrees, the circulation is centrifugal. These facts have been confirmed radiographically.³⁷ We do not know, and apparently have no certain means of finding out, the effect at any given moment of the anastomoses close to our point of injection. Although most who practise the treatment try to empty the vein of blood after the needle is in the lumen and before making the injection, so as to bathe the endothelium with the concentrated drug, and then either let the patient lie or stand a few minutes or a pad and bandage is applied, they have no sure knowledge that the injection has not gone quickly into a deeper loop of vein or been rapidly diluted by blood from another channel. It seems to me unnecessary to blame the keeping properties of a solution when these other obvious variables are present. These variables also help to explain the excellence of the results in general, because the injection

reaches though doubtless in a less concentrated form, the smaller tributaries, and especially the anastomotic and perforating branches which join the deep veins. At that moment the dilution becomes excessive. The respiratory change noticed by Barber²² may also be intimately related to the matter. That we have not got the whole truth yet is also clear from the case recorded by Wilson²³ of the disappearance of a group of varicose veins below the knee six weeks after six punctures had been made for the withdrawal of blood. Sir William Bennett²⁴ recorded six cases of the spontaneous disappearance of large varicoeas after injury to them. Both these observations are interesting also in view of the treatment of aneurysm by scratching the inner wall of the sac with a needle, for in such cases the amount of clot formed has been minimal or nil, and no embolism has ever occurred in the absence of sepsis.

The danger of embolism in aseptic cases of varix treated by injection is evidently very small. Olson²⁵ records one in a woman, aged 33, on the fifth day after the second injection of salt solution and calurose. At the necropsy the thrombosis in the internal saphena was found to have its end broken off and pulmonary embolism was present. McPheeters²⁶ noted that two deaths had been recorded up to October, 1927, one due to fat embolism and one due to mercurial poisoning. Hohlbaum²⁷ had a fatal case in a man, aged 54, who was injected with 80 c.c. of an isotonic solution of iodine, and had been kept in bed. A Meisen²⁸ up to January, 1927, had seen two cases of pulmonary infarction, both in association with doses which he considered to be too large, and two others in patients with phlebitis. There were three sloughs in his series and one severe haemorrhage, but as 133 out of 135 ulcerated legs healed, many of the ulcers being of long clinical duration, and as eczema cleared up rapidly, the complications are hardly worth considering. Jorgensen²⁹ has seen symptoms resembling serum sickness after sodium salicylate, and others have had similar experiences, but they are rare. As an offset we have the many thousands of cases of excellent results now recorded everywhere, and apparently likely to be permanent.

Jeannel concluded his report in 1910 by insisting that it was of the first importance to determine in each case whether either the superficial or the deep reflux, or both together, were concerned. Trendelenburg's operation was indicated in the first case, and femoral or crural excision in the second. When both refluxes were concerned total saphenectomy was required. Diagnostic errors were the cause of disappointing results. As suggested in 1921,³⁰ we need a clinical plethysmographic method to give us more accurate information about the carrying capacity and general state of the deep venous circulation than do the Trendelenburg, Perthes,³¹ or other muscle pump and clastic stocking tests. This is particularly required in women and in patients with a history of deep phlebitis. The hydrostatic treatment of ulcer by Unna's paste depends upon it. In the meantime, by applying the injection treatment in the manner indicated by Jeannel's collected results, we shall attain a much larger measure of success than by operation, and at very much less risk and inconvenience to the patient.

RESULTS OF THE INJECTION TREATMENT

It is quite common now to obtain an almost complete obliteration of a valveless internal saphena system after one injection. The procedure is as follows:

The patient stands on a chair near a table and a single band tourniquet is lightly applied around the upper part of the thigh, to help to prevent the veins from emptying too rapidly during recumbency. The patient then lies down on the table and the vein is entered preferably above the knee or in the main trunk of it below the knee. The tourniquet is loosened, the vein is emptied of blood near the needle, and a finger is placed on it above the middle of the thigh 2 to 6 c.c. according to the size of the veins, of 30 per cent sodium salicylate with 10 per cent sodium chloride solution (P.D. and Co.) are injected preferably towards the groin. The limb is elevated to 30 degrees for three seconds, and then the patient rises slowly and stands on the chair. The finger is removed and the charge of solution sweeps downwards into the saphena system. This is painful for half a minute. The patient describes the pain as continuous and stinging or as cutting, lancing or cramp-like and feels it travelling down the leg to the foot. These omens are favourable. By letting the patient lie down at this stage and again elevating the limb for

a few seconds the solution may perhaps be tipped back again or kept a little longer in the saphena. Active muscular movement as once sucks the solution away and dilutes it rapidly. No bad effect has been noticed. Sometimes the solution must miss out living varicose groups because these may require separate injections a week or a fortnight later, when the effect of the first injection has become manifest. At this time also the external saphena system, or the large anastomotic vein from the external to the internal system which is often present in front below, or above or behind the knee may be injected. A week after the first injection the internal saphena system is generally hardening from the middle of the thigh to the lower third of the leg. Exceptions seem to be explicable by the well known common sites of the chief deep anastomosing channels which dilute the solution.

Taken as a whole this method has answered very well and seems to me to be better than beginning at the distal radicles and working against gravity with multiple injections. The results have been as follows:

In the first seventeen limbs sixty injections, each of seldom more than 3 c.c., were used and one small scab formed. In the next twenty limbs only forty seven injections were required of 4 to 6 c.c. seven of which were in a limb in which the excessive blood volume diluted the solution quickly. Three small scabs formed in these limbs. In nearly all the limbs the degree of varicosity was marked and there was an impulse to the ankle on coughing. Tiredness, weight fullness and cramp had been the chief symptoms.

In one limb with a vein of small blood volume an injection of 2 c.c. was sufficient to cure. In one with a large blood volume one of 6½ c.c. cured. In three limbs with large blood volumes one 5 c.c. injection cured in each case. In one case an injection of 6 c.c. cured the internal saphena and one of 3 c.c. the external. In another case an injection of 6 c.c. (and 5 c.c. for a large cyst) cured. In one instance the walls of an anastomotic vein stuck together with no sign of thrombosis after the introduction of 2½ c.c. In two cases with large blood volume injections of 5 c.c. above the knee and 5 c.c. near the ankle resulted in cure. In one case injections of 6½ c.c. and 5 c.c. cured and in another instance the introduction of 5 c.c. and 3 c.c. cured the condition. By cured is meant that the whole of the visible internal saphena system which was the one chiefly involved became thrombosed in a week or a fortnight from the middle of the thigh to near the ankle and that in five weeks there was, for practical purposes, no sign or symptom of the disease.

These results show clearly that the hydrostatic principles of Trendelenburg (Brodie) and the operative indications of Jeannel are the lines along which the injection method should be practised when using salicylate-saline solution. Whether this method is possible with smaller injections such as with the quinine solution or not remains to be settled. The larger volume of the salicylate-saline solution is certainly more manageable in this respect and is yielding the results with negligible risk and little inconvenience, results which are so much better than were possible by laborious and somewhat risky operations that operation seems to be no longer justifiable except in certain very isolated cases.

MEDICAL, SURGICAL, OBSTETRICAL.

THE TECHNIQUE OF INJECTIONS FOR
VARICOSE VEINS

INJECTIONS for varicose veins should not be undertaken in a haphazard manner nor by one who is unfamiliar with other intravenous injections, he should, preferably, have watched the procedure in the hands of others before attempting it himself. Should that not be possible the following description of the essentials may be of help to him.

After a complete examination of the patient, including the heart, lungs, urine and internal organs—especially the pelvis in women—the legs should be observed first in the upright and then in the recumbent position. Ask the patient to take a deep breath and look for the effects of respiration in the enlarged veins of the thigh—if they are present—and note its effect either by sight or touch with the finger applied over the vein.

Select the lowest dilated vein or swelling in it this corresponds to the site of incompetent valves. With a pledget of cotton wool dipped in tinct iodine paint the skin over the proposed site for injection and well beyond it. Remove the iodine with spirit. Disinfect the hands with soap and water, and rinse with spirit.

Use an all-glass 5 c cm syringe with a nickel needle 0.45 mm. in diameter and having a very sharp, short, bevelled point. It must be boiled before use.

To insert the needle exactly into the lumen of the vein is of primary importance. Two methods can be used—namely, the patient either stands or is lying down. The former position will be useful for small veins, which are often associated with ulcers or eczema, they cause greater pain and give rise to more symptoms than do the larger ones which are easily punctured with the patient lying down. If the patient is standing, the needle is alone inserted as soon as blood begins to drip from it he lies down. Connect the already filled syringe to it and inject the fluid while the patient is taking a deep breath (*British Medical Journal* April 7th p 594). If the vein is large insert the needle already attached to the syringe, and watch for blood to flow into the barrel, then—and then only—inject. In very large veins I sometimes put the patient in the Trendelenburg position after inserting the needle and then inject. The injections are always given towards the trunk often, however it will be seen that the vein has been blocked below the site of puncture, and not, as one might expect, above it. Three or more injections can if desired be given at the same sitting but it is well to test the reaction obtained at the first one by giving only one injection of from 2 to 5 c cm of the solution.

As the injection proceeds ask the patient repeatedly if he feels any stinging or burning if he does stop the injection at once, for either the needle has become displaced or the fluid has ruptured a dilated vas vasorum causing leakage into the surrounding perivascular tissue. Should a swelling appear over the vein during the injection, with or without pain, stop the injection at

once. This pain however, must not be mistaken for cramp, which is felt in many cases and is of good omen as regards end results, it only lasts a few minutes and passes off—the “wasp sting,” on the contrary, increases. As soon as the injection has been given wait for a full minute, then remove the needle quickly, and apply at once firm pressure over the site of puncture with a piece of cotton wool to prevent any of the blood charged with the solution from escaping into the tissues. This detail is of great importance, it is one way of preventing pain and a possible slough.

After the injection the patient should be quiet for ten to fifteen minutes while the site is dressed. The puncture is closed with a drop of newskin or collodion. Five or six inches of a 3 or 4 inch bandage is soaked in a solution of zinc oxide, glycerin, and mucilage of acacia in 2 or, and applied, folded three or four times, to the part injected. This is kept in place by a few turns of the bandage and a safety pin, and is not removed till the next visit, the object being to lessen any inflammatory reaction.

The number of injections required varies considerably in some cases one or two in others ten to twenty are necessary. The length of the vein occluded is also variable. I have seen one injection of 5 c cm, given below the knee, obliterate the whole of the great saphenous vein as far as the femoral ring. In other cases the same amount only blocked 3 or 4 cm of the vein, on an average 5 to 8 cm are dealt with by each injection.

The injection itself is painless except for the prick of the needle. Cramp is fairly frequent on the whole but gives no indication from its severity as to the amount of vein acted upon it, however, proves that the injection has been effectual. Stinging or burning should never occur if it does, withdraw the needle at once and inject 5 or more c cm of sterile water into the surrounding soft tissues in the hopes of diluting the caustic solution and preventing a blister the forerunner of a slough which, if formed takes some weeks to heal. Sloughing is the only serious complication likely to happen most often it is due to some fault in technique but at times it seems to be unavoidable even while taking the greatest care. Periphlebitis (aseptic), also endophlebitis may occur, although these are painful they are sure signs that the vein has been obliterated. The same condition can result without pain. If the reaction is acute prescribe rest for a day or so the application of heat to the part gives relief and the redness and swelling quickly disappear, especially if liberal applications of the zinc lotion are made several times daily. Some patients are liable to feel faint at the first injection though not subsequently as a rule, this does not prevent the injections being given.

I have used this technique with most gratifying results for more than three years in a considerable number of cases, employing at first a solution of pure NaCl of from 15 to 20 per cent, but latterly of 15 per cent. My reason for using this substance to the exclusion of all others is that (1) it is very effectual, (2) it can easily be prepared, (3) it can hardly be called a drug, and precludes any possible idiosyncrasy on the part of the patient, (4) if required, from 5 to 15 c cm can be given at one sitting without fear, and (5) the solution is self-sterilized. Small or large veins can be injected and cured by its use. I can see no advantage gained by using other substances, which can and have caused untoward symptoms of a more or less serious nature.

“HERNIA” INTO THE BROAD LIGAMENT

ALTHOUGH there are many possibilities of strangulation of the bowel through intra-abdominal peritoneal sacs, the following record of a case to which I have found no parallel in the literature may be of general interest.

A multipara had been operated upon nine years previously for a strangulated left femoral hernia. The bowel then implicated was found to have two perforations which were infolded. A complete recovery was made and the patient regained good health. Recently she was admitted to the hospital again with abdominal pain, distension, absolute constipation, fecal vomiting and other signs of acute obstruction, but no cause for the condition could be deduced. Owing to the rather prolonged period of onset (the symptoms had been coming on for four days) it was thought that adhesions might be responsible.

An exploratory abdominal section was performed through a left paramedian incision. The major part of the small intestine was found to be greatly distended. The obstruction proved to be situated in a lower loop of the ileum, a portion of which approximating to a Richter's hernia was found to be strangulated at the neck of a peritoneal invagination into the posterior aspect of the left broad ligament. The neck of the sac was incised thus releasing the bowel which could not be withdrawn otherwise and was then sewn up. An uneventful recovery was made by the patient.

I am indebted to Mr Reid for permission to record this case.

THE DURATION OF STAPHYLOCOCCUS AUREUS SEPTICÆMIA

The reference in the *British Medical Journal* of August 25th (p. 348) to the Bundaberg disaster is such as to make the duration of *Staphylococcus aureus* septicæmia a matter of considerable clinical interest. The Commission appointed to investigate the disaster expressed the view that forty-eight hours was the usual minimum duration of fatal staphylococcal septicæmia, whereas certain of the children at Bundaberg who were inoculated with what was to all intents and purposes a strong culture of *Staphylococcus aureus* died in twenty-four hours. Children, of course, would tend to succumb more quickly than adults, as the dose per kilogram of body weight would, *pro facto*, be relatively greater. But that *Staphylococcus aureus* can kill quickly even an adult the following instance will show.

G.D., a female patient of the East Sussex County Mental Hospital suffering from recurrent mania was noticed by one of us (W.D.) to have a boil on her neck on the evening of August 21st. On August 22nd at 2.30 a.m. she complained of pain was excited and noisy and was given a draught of paraldehyde at 5.40 a.m. She slept until 6 a.m., and then again complained of pains all over. She was found to have a temperature of 100° F. There was some coughing and the pain persisted; the latter was especially referred to as coming from under the left breast and she expectorated a little from then onwards. She was removed to the infirmary at 8 o'clock that morning. Her temperature never rose higher than 102° F. She became seriously ill and very livid in colour and the medical officer on duty was called to her at 6 a.m. on August 23rd when her temperature fell to 99°. She died two and a half hours later; the duration of illness being thirty hours.

Autopsy Features of Note

Lividity of face, lips and ears; a recent crop of medium-sized boils on the back of the neck, one of which was sloughing.

Head.—Sero-sanguinous exudate below the scalp, having a circular but larger area with a centre corresponding to the sloughing boil. Intense pink vascular congestion of the meninges. Wasting of the cerebral convolutions. No abscesses.

Thorax.—The right pleura was adherent at the apex. Sparse scattered petechiae were present over the visceral pleura. The left pleura showed similar petechiae. One superficial area of necrosis was seen a quarter of an inch in diameter. The lungs were of a deep red colour and showed here and there darker coloured patches suggesting early infarction. The pericardium showed petechiae on the visceral aspect. The heart was of the renal type, the muscle being hypertrophied and fibrotic, and the aorta showed early atheroma.

The blood was fluid.

Abdomen.—The peritoneum showed intense pink engorgement. The liver was soft and fatty and the spleen diffusely and slightly enlarged. The kidneys showed changes usually associated with chronic interstitial nephritis; the capsule stripping with difficulty, reduction of the cortex and an enlarged pelvis full of fat. Signs of fatty cortical degeneration were also noted.

Cultures taken with due cauterizing precautions from the spleen and lung showed a pure heavy growth of *Staphylococcus aureus*.

Comments

The mental patient has notoriously poor resistance and often succumbs early to infection. The general metabolism is usually upset, and most patients suffer from mild chronic acidosis. At the same time it is unusual for a staphylococcal septicæmia to be so quickly fatal, thirty hours being a remarkably brief illness for an adult. In the light of the Bundaberg fatalities the case has, however, a topical interest.

We are indebted to Dr. F. R. P. Taylor, medical superintendent of the East Sussex Mental Hospital, for permission to publish the case.

Pathologist, East Sussex County Mental Hospital.

TROPICAL LIVER ABSCESS ACQUIRED IN ENGLAND

The occurrence of a case of tropical liver abscess in a man who had not travelled outside Great Britain appears to be of sufficient interest to merit recording.

The patient, a man aged 49, was caretaker at the Burnley public abattoir. He became ill ten or eleven months before admission to hospital. The first signs of infection were diarrhoea (four to six motions a day) and the passage of much mucus. About two months later he noticed a quantity of blood and slime in his stools and complained of pain and tenesmus; the straining did not relieve the pain, but tended to make it worse. Restriction to milk diet for six weeks relieved the diarrhoea for a period of eight weeks, during which time he felt quite well. Then followed another attack of diarrhoea (five to six motions a day), but this

time there was no pain, tenesmus, or blood in the stools, only a little mucus at the end of the motion. He had no pain, but there was slight tenderness over the liver, and probably slight enlargement of this organ, since a diagnosis of gall-stones was made. Later he was suddenly seized with severe pain over the liver, as if someone had stuck a knife in him; he also began to complain of pain in the right shoulder and upper arm. The pain over the liver came and went for about six weeks after its appearance and frequently woke the patient at night. The diarrhoea also came on in attacks. Hypnotics were given to subdue the pain and finally the patient was admitted to the Victoria Hospital, Burnley. During his illness he had lost weight.

On admission he was thin and emaciated, the skin was muddy, and he looked very like a man with advanced carcinoma. The skin had lost its elasticity. The abdomen was very thin, but a bulging was seen in the right hypochondrium extending into the epigastrium. There was no pain over the liver, but there was slight tenderness. The liver was greatly enlarged and its edge extended half an inch below the level of the umbilicus. The enlargement was uniform and the edge was smooth on palpation. Nothing else of note was found in the abdomen. A rectal examination disclosed no tenderness, and no growth was felt. The examining finger returned covered with mucus.

He subsequently complained of such intense pain over the liver and in the epigastrium that he could not sleep without morphine. The diarrhoea persisted and a large red oedematous tender swelling developed over the right costal margin. On x-ray examination a large shadow was seen in the tender area, the shadow being nearly all the liver area, on palpation. Screening showed that the shadow was pushed up and did not move with respiration.

Entamoeba histolytica were found in the stools. At an operation a large liver abscess was opened and about two pints of chocolate-coloured pus was drained off. No amoebae or cysts were found in the pus which was examined three times during the next six days. After the operation he was given saline solutions, farinaceous diet, pulvis ipecac. co. and emetine bismuth iodide grain 1 i.d. The diarrhoea grew worse, and injections of emetine hydrochloride were tried. Two days after the operation leucop developed which was temporarily relieved by oil of cloves, but in spite of all treatment the patient went rapidly downhill and died seventeen days after the operation.

This case was especially interesting in that the patient had never been abroad and did not know anyone who had suffered from or been in contact with amoebic dysentery. The source of infection was not traced. Another point was the difficulty of diagnosis, and this was only finally accomplished after a microscopic examination of the stools had been made. At different stages of the illness, the condition appeared to be gall-stones, carcinoma, and subphrenic abscess in turn. It would seem well to make a routine examination of the stools in all cases of obstinate diarrhoea, which persists without obvious cause in spite of the usual treatment.

I am indebted to Mr. Callam, honorary surgeon to the Victoria Hospital, and also to Dr. Haworth, honorary physician, for their permission to publish this case.

Bradford

J. CAMPBELL GILROY, M.B. Ed.

LARGE OSSICLES IN BOTH KNEE-JOINTS

The following case of ossicles in apparently healthy knee-joints seems to be worthy of record.

A soldier while performing his duties in his company kitchen, was suddenly seized with acute pain in the right knee-joint. He was a tradesman from Westmorland and though accustomed to travel over rugged hillsides and moorland, had never had any previous trouble with either knee-joint.

On examination, some hours after the attack of pain, a slight effusion was present in the right knee-joint and a large bony body was felt in the outer and anterior portion of the suprapatellar pouch. This body could be moved across the synovial pouch from side to side. Examination of the left knee revealed a similar body in the same position.

As soon as the slight synovitis of the right knee had subsided the ossicle was removed by an incision on the outer side of the patella; the joint was then closed in layers in the usual manner. For convenience of nursing the left ossicle was removed a few weeks later.

Both ossicles were lying quite free in the joints and had no connexions or adhesions whatsoever. They were oval somewhat the shape of a Brazil nut in section, a little more than one and a half inches in their longest diameter and eburnated on their posterior faces where they came into contact with the femora. The synovial membrane in contact with them was vascularized and velvety in appearance.

Convalescence was rapid and the patient walked perfectly as soon as allowed to do so.

The interest of this case lies in the size of the ossicles and the fact that the condition was bilateral. No current theory of the genesis of intra-articular bodies seems adequate to explain such a condition arising in a healthy man with perfectly healthy joints.

Reviews.

WILLIAM BATESON

To all British biologists the death of William Bateson seemed at the time calamitous. It left us leaderless, and as yet there is no one who can worthily fill his place. We knew him to be a really great man, but we did not know the quality of his greatness. And so it was that for us this book, *William Bateson, F.R.S., Naturalist*,¹ was necessary. It explains so much. Mrs. Bateson, in giving a finely drawn sketch of her husband, unwittingly allows us to recognize the fact that much of the encouragement and practical help which made his pioneer work possible and successful came from her. The book is inspiring reading for the professional scientist. In its pages it can be seen that really first-class scientific work can be done under the most unsatisfactory circumstances, provided that the man who does it is himself first-rate. But we would specially recommend it to the wives, actual or prospective, of the men who serve science, for it will explain to them, as no other book can, the kind of personality that is exhibited by the man who loves his work more than anything else in life, and the need that such a man feels for spiritual companionship and practical help.

The book is built up of a memoir, fourteen selected papers, described by Bateson himself as "more or less lawfully begotten by Monodism out of Common Sense *me obstetricante*" and classified as digestible, for the eupeptic only, and indigestible, five educational essays, and three reviews, the whole constituting a vivid portrait of a rare personality. "To observe with him was an instinct, and to reflect and criticize, a lifelong habit. Never for one moment in the interest of detail did he lose sight of the central quest. For him no method, nor any branch of research, was an end in itself or more than a useful tool to chip away with. He dreaded the pedantry and increasing narrowness of each branch of biological research almost more than he dreaded and despised the public ignorance." How magnificent an epitaph and how well deserved! "Faith in great work," he wrote, "is the nearest to religion that I have ever got, and it supplies what religious people get from superstition. There is also this difference, that the man of science rarely hears the tempting voices and very seldom needs a stimulant at all, whereas the common man craves it all the time. Of course, there is great work that is not science—great art, for instance, is perhaps greater still, but that is for the rarest and is scarcely in the reach of people like ourselves. Science, I am certain, comes next, and that is well within our reach." How fine a creed and how splendidly arrogant! The scientist shares in the glory of his science and is proud in his humility.

The story of the earlier years spent in the experimental study of heredity and variation is fascinating. Surely no one ever met with so much discouragement. Bateson saw in this new science of genetics—he coined the word in 1905—the most promising means of advancement of pure science, and quickly recognized that such knowledge, if pursued, must ultimately lead to amelioration in the conditions of human life. It is true that he himself was entirely engrossed in the purely scientific aspect and interest of the work, and that he was bored rather than pleased by the practical application of the knowledge he was acquiring, since he feared that the application of genetics to agriculture would attract to research the wrong kind of worker, whose motive was gain or profit for someone. It has! But he was alone in his vision. Application after application for grants-in-aid was unsuccessful, rebuff followed rebuff, and at length he learnt to be wary in giving expression to his natural hopefulness. It is of interest to note that he declined an invitation to transfer his activities to America in 1902 for the reason that at that time he was still hopeful of starting an experimental

breeding station in England, and that he had to wait eight years before he got it. He, like the rest of us, was forced to spend much of his time and energy in seeking adequate endowment, for he recognized that this was as important as extending the compass of the work.

There is a letter (p. 102) which illuminates much in Bateson's history that invited explanation. It records his emotions on hearing of Weldon's death. He acknowledges his great indebtedness to Weldon, and then goes on to say, "if any man ever set himself to destroy another man's work, that did he do to me." This statement, we think, is justified. The bitterness of this war between biometrician and Mendelian has not yet completely evaporated.

In 1926, in a letter to the council of the John Innes Institution, Bateson touches upon two matters of the greatest interest to those of us who knew him. The chief centre of activity in genetics had shifted from where Bateson was to America—to Morgan and his school—a real calamity for British biology. The reason is a simple one. The amazing rate of development of genetics in America was determined primarily by the unique suitability of *Drosophila* as experimental material. Bateson was handicapped by the reaction of his many failures to obtain a proper recognition for his science in this country, and by the fact that he had become accustomed to work with a material that could not compare with *Drosophila*. Mendel was permitted to solve the riddle of heredity because the edible pea revealed the clue to him. In this letter he refers also to the fact that there was at Merton no one to succeed him. He who had given a name to a science had failed to form a school. The reasons for this would seem to have been that Bateson would have no one but men of first rate ability around him, and that these were attracted to genetics but rarely. He meant to repair the deficiency, but died a month after the letter was written. His body was cremated and his ashes scattered. In ten years or so the monument to Bateson's greatness will have taken shape. His labours, seemingly unproductive at the time, have made the path of those who follow him not more smooth but indeed pleasant.

This is a fine book, absorbingly interesting and delightfully written. It may well be prescribed for any intelligent patient suffering from debilitated faith in the possibilities of human development.

C

PHYSICAL DIAGNOSIS

Books on clinical diagnosis too often consist of a rather dreary catalogue of the physical signs which may or may not be elicited in health and disease while most authors who elect to write dissertations on this subject devote so much attention to the thorax and the abdomen that scant notice is given to other regions of the body. In presenting *Physical Diagnosis* Professor C. P. JEMESON has made a welcome break with the usual traditions, and the result is a very comprehensive and at the same time readable volume which covers all the organs and systems of the body and directs attention to the organism in its entirety. At the same time he has enlivened his chapters by brief references to regional anatomy and historical notes on the original discovery and application of different physical signs. He maintains strongly that physical investigation is, and must remain, the primary fundamental method of diagnosis. The increase of laboratory and instrumental aids to diagnosis has made the accurate determination and interpretation of physical signs of even greater importance than was formerly the case, and has increased rather than diminished the responsibilities of the man personally responsible for the individual patient.

The introductory chapter is devoted to a short review of the contributions to clinical methods of such masters as Sydenham, Laennec, Skoda, Flint, Corrigan, Graves, Mackenzie, Osler, and others. There is a useful hint on the importance of ensuring that the examination of the patient should always be undertaken in a sufficient light. Then follows a chapter on general physical characteristics.

Physical Diagnosis, By Charles Phillips Emerson. A.B. M.D. London: J. B. Lippincott Company, 1928. (Med. 8vo pp. xv + 551; 324 illustrations 35s. net.)

¹ William Bateson, F.R.S. *Naturalist*. His Essays and Addresses together with a short Account of his Life by Beatrice Bateson. London: Cambridge University Press, 1928. (Demy 8vo pp. ix + 475; 4 plates. 25s. net.)

in which the types of growth, abnormalities of growth, and apparent ages, and the general attitude of patients are discussed and commented upon. Succeeding chapters deal with the regions of the body taken in order, the general body surface including a review of the more common affections of the skin, the head, spine, thorax, abdomen, and the extremities. The descriptions as a rule are clear, and the explanations as to how and why a given condition produces a certain sign are sufficiently definite to stamp them on the memory of the reader.

We might have expected to find in a work of this kind some reference to the theories of the causation of visceral pain—work which, initiated by Mackenzie a good many years ago, has been elaborated by other investigators, but no mention is made of this fascinating field of study, for the clinical observer. Such other criticism as we might be disposed to offer would be that perhaps the author has attempted to cover too much ground in his interpretation of the title chosen, physical diagnosis, that his book might almost be described as a textbook of medicine compiled from a new point of view. If this be a fault it is decidedly a fault in the right direction. The book is liberally illustrated with charts, diagrams, and reproductions from photographs. The photographs, on the whole, are very successful, except those illustrating diseases of the skin, in this instance photographs can never convey an intelligible message to the student, and only very rarely do they do so to one who is familiar with the characteristics of the lesion it is sought to depict.

PEDIATRICS

It is always refreshing to find a familiar subject approached on unusual lines, and in *Recent Advances in Diseases of Children* Dr W. J. PEARSON and Dr W. G. WYLLIE have certainly a great number of fresh ideas to bring forward. The book differs in some respects from other members of the series, for it really covers the whole field of pediatrics, and is from this point of view a well documented and up-to-date manual of the subject. Its unconventionality begins in the first chapter, where, under the heading of "A philosophy of disease," the authors take stock, as it were of the present position. They describe two contrasted types, the "lymphatic" and the "acid," basing the classification on clinical and biochemical data. The normal child, they say, "presents a mean between the two," and these two tendencies are present in every child, representing the "soil" wherein the reaction to disease processes takes place. This view, along with a very interesting analysis (at times difficult to follow) of the chemical reactions of the body, is worked out in some detail in this introductory chapter. The impression is left that the logic is a trifle daring even if the chemistry is sound—of which we are not always quite sure. Thereafter the book follows the usual programme so far as subject matter is concerned, it is in their return to the theories and implications of the introduction that the authors' unconventionality breaks through. At times, indeed, the views expressed become rather startling, and we find it impossible to follow such a statement as occurs on page 321, dealing with fibrosis of the lung: "The main reason for non resolution and fibrosis lies in a chemical fault, an excess of acid in the blood." The rest of the section on this subject is very good, and it is typical of the whole book to find a mass of sound teaching in the middle of which appears a loose phrase of which common sense rebels. Do the authors believe that there is ever any acid in the blood, for less "excess" of such acid? The opinions on tonsils and adenoids are well balanced, and the chapter on the nervous system is good. Modern views on nephritis are well summarized, and the very complex subject of the blood disorders of children is cleverly treated. Enough has been said to indicate the scope and standard of the volume, and it should certainly be read by those interested in modern medicine. It will repay study, despite its controversial nature and its loose chemical terminology.

GASTRO-INTESTINAL DISEASES

THESE lectures delivered at the James Mackenzie Institute for Clinical Research at St Andrews on *Gastro-Intestinal Diseases* during the winter session of 1927 have now been published under the editorship of Professor DAVID WATFISTON. The honorary director of the Institute—Dr A. Matland Ramsay—opens the series with an account of the ocular manifestations of gastro-intestinal disorders, among which he includes iritis due to dental infection, and to constipation with the resulting intoxication and infection. The other lecturers were imported, and include Sir Lenthal Cheate, who applies some recent views upon carcinoma, especially of the mamma, to the colon, and Dr D. J. Spriggs of Ruthin Castle, whose lecture on the symptoms of gastric cancer is illustrated by twelve excellent diagrams, he considers that the only absolutely constant sign is arrest of peristalsis in the site of the growth, as shown radiologically. Dr J. B. Orr, director of the Rowett Research Institute, Aberdeen, in discussing the influence of diet on the physiology of the alimentary canal, gives the results of his own experience of starvation and of experiments at his Institute. Professor John Fraser's account of the diagnostic value of superficial pain is based on much thoughtful observation, and Dr Matthew's discussion of the significance of haematemesis utilizes his analysis of cases in the Edinburgh Royal Infirmary. Professor D. P. D. Wilkie's lecture on gall-bladder disease and gall-stones contains a criticism of duodenal drainage and an appreciation of Graham's tetraiodophenolphthalein method of diagnosis. Dr R. O. Adamson of Glasgow writes at length on the symptoms of dyspepsia as met with in general practice, and Professor Archibald Young enters fully into the surgical aspects of gastric and duodenal ulcers. The subject of dissemination of malignant disease, especially in the abdomen, was wisely entrusted to Professor Robert Muir, who provides much information in a suggestive manner, and Sir John Murnoch warns the reader against some of the pitfalls in the diagnosis of acute abdominal disease.

OVARIAN GRAFTS

THE publicity given of late to the grafting operations performed by Dr Voronoff has rendered it desirable that there should be some work which would summarize all the available information on this subject. A recent book by Dr PETTINARI on ovarian grafts, although not written for this purpose, does provide such a book of reference for at least a part of this subject, as its title indicates, it is concerned only with ovarian grafts and the endocrine action of that gland. The volume may be regarded as consisting of two parts. The first deals with the histology of the ovary in all its cyclical transformations, with feminization, experimental hermaphroditism, revitalizing grafts, the origin of ovarian hormones—specific and general—and their relationship with lactation and the mammary gland, sexual characters, and so on. The second part is devoted to the application of ovarian grafts, and here the author discusses in some detail the important question of the role of the ovary as a ductless gland both in physiology and pathology. Other chapters are devoted to the indications and contraindications for grafting, and the technique to be employed. Finally, the much-discussed problem of the transplantation of the ovaries of monkeys to women is reviewed. There is a large bibliography, the illustrations are numerous, and a very concise list is given of the author's own conclusions. Dr Pettinari was assistant to Voronoff for some time, and has himself had a considerable experience of gland grafting. His volume may therefore be regarded as fairly representing the views of the Voronoff school on this aspect of the subject, and not merely as a review of the literature. The book is written clearly and moderately, and seems reasonably free from bias, the reader is given a fair idea of those cases in which ovarian graft might be of use, the results which would probably be obtained, and the best

² *Recent Advances in Diseases of Children*. By Wilfred J. Pearson D.S.O., M.C., D.M., F.R.C.P. and W. G. Wyllie M.D., M.R.C.P. London: J. and A. Churchill, 1928. (5½ x 8½ pp. viii + 593, 18 figures, 18 plates. 15s.)

¹ *Gastro-Intestinal Diseases*. Lectures delivered at the James Mackenzie Institute for Clinical Research, St Andrews. Edited by Professor David Watfiston. M.D., F.R.C.S. Ed. Oxford Medical Publications. London: Milford Oxford University Press, 1928. (Demy. 8vo pp. viii + 278, 23 figures, 10s. 6d. net.)
² *Greffes Ovariennes*. Par Vittorio Pettinari. Paris: G. Dolin, 1928. (6½ x 8½ pp. 491, 181 figures, 70 fr.)

technique to be adopted. It is well produced, and contains nearly two hundred excellent figures, most of them original, illustrating the anatomy and histology of the ovary, the results of the operations both to the gland itself and to the subject, and the technique of the various types of operation.

GUY'S HOSPITAL REPORTS

AFTER some lines of verse entitled "Do Mortu Coidis, 1628-1928," reprinted from the *Times*, the third quarterly instalment of the *Guy's Hospital Reports*,¹ which contains twenty-two articles, begins with M. A. J. McNair's interesting account of James Blundell, obstetric physician 1818-34, who a hundred years ago performed the first successful hysterectomy for cancer in this country, and did much in regard to blood transfusion. A particularly thoughtful and philosophical article by Dr J. A. Ryle on anger animi or the sense of dying shows that it occurs in Gowers's vaso-vagal attacks as well as in angina pectoris, and that in a patient with the former kind of seizure it may occur over a period of thirty years without modification, although the patient now realizes that she will not die in them. There are several papers on nervous diseases. Mr A. B. Kettle writes on multiple gummata of the brain, Mr O. Plowright on familial claw-foot with absent tendon-jerks and cerebellar disease, and a case of route ascending myelitis is recorded by Dr R. L. Waterfield, who also contributes three other short papers on two cases of subarachnoid haemorrhage, Biot's respiration associated with obstruction of the superior vena cava of obscure origin, and the alternation and subsequent combination of met- and sulph-haemoglobinæmia in one patient. The last of these papers is followed by Dr M. O. Raven's report on a case of methaemoglobinæmia due to poisoning by antikamnia (acetanilide), with a note by Dr J. A. Ryle. A simplified method of detecting megalocytosis is described, with illustrations, by Dr F. A. Knott. Drs J. M. H. Campbell, G. O. Mitchell, and A. T. W. Powell give an account of their experimental investigation by way of fractional test meals on the influence of exercise and hot baths on digestion. Mr E. H. Rocho discusses the factors determining why empyema wounds heal less satisfactorily than drainage wounds in other parts of the body as a preliminary to his article on suction in the treatment of empyema. Drs E. P. Poulton and W. W. Payno describe an unusual type of insulin reaction in a diabetic woman who had a high renal threshold and frequently had symptoms of "hypoglycaemia" when the blood sugar was falling, even though the values were often over 0.25 per cent. Dr W. L. Watt gives a regional series of cases of malignant disease treated with deep x-rays, Mr J. W. Shackie figures a stage in the development of *Taenia echinococcus* seldom seen, Dr N. Burgess writes on calcium metabolism in skin diseases, and there are five cases of interest (the fifth series) from "Clinical" ward. Dr J. F. Venables records a case of Hodgkin's disease primary in the small intestine causing intestinal obstruction—an event which appears to be unique.

NOTES ON BOOKS

THE popularity of the late Professor STRÜMPFEL'S textbook of pathology and therapeutics² shows no abatement, and Professor CARL SEIFARTH, who has been for some time associated with this publication, has maintained the high standard of previous issues. We reviewed the first volume of the twenty-sixth edition in July, 1927, the second volume of this edition appeared in the following October. We have received the first volume of the twenty-seventh edition, and the second volume is expected shortly. Under such conditions it is difficult to say more than that the book deserves the favour in which it is held, though the habit of limiting the index to the second volume of each edition is a little inconvenient in the circumstances.

¹ *Guy's Hospital Reports*. Vol. 78 (Vol. 8 fourth series) No. 3, July 1928. Edited by Arthur Hurst, M.D. London: The Lancet, Limited (Med. Sec. pp. 253-378, 2 full plates, 15 figures. Annual subscription 12s. 6d. for volume of four).

² *Therapie der Krankheiten des Menschen*. Vol. 27, 1928 (Suppl. 1-4, 1928, 202 figures, 6 tables, M.50). Part 1, 10 plates, M.25).

In his book *Man and Sunlight*,³ Major HANS SURÉN, formerly chief of the German army school for physical exercise, advocates enthusiastically the value of exposure of the whole body to sun and fresh air. He supplies numerous illustrations of the various exercises and games which can be employed, and, in addition to his main argument, the book contains many practical hints and warnings. The volume may be considered a timely protest against certain unhealthy sequels of city life, but it is a little difficult to see at present how his recommendations could be adopted in this country on any appreciable scale.

A copy of the obstetrical yearbook⁴ by H. VIGNES and B. JEAN, with the collaboration of V. ROBIN, containing the important papers that appeared during 1925, has reached us. This gives a short analytical review of the papers by writers on this subject in France and other countries, and is interesting as containing a special section at the end on veterinary obstetrics. It has also some special articles by Dr Henry Vignes, which might be useful to anyone working at the subjects he takes up for critical review. They include researches on the function of the placenta, the pancreatic function during pregnancy, the Wassermann reaction in obstetrical practice, cancer in pregnancy, and the anaemias in pregnancy and the puerperium.

Major E. E. AUSTEN, Keeper of the Department of Entomology in the British Museum (Natural History), has revised, for its third edition, his pamphlet on *The House Fly: Its Life History, Importance as a Disease Carrier, and Practical Measures for its Suppression*,⁵ incorporating many minor additions made to knowledge in the two years that have elapsed since the publication of the second edition, which was reviewed on May 29th, 1926 (p. 906). The new matter relates mainly to alternative methods for the suppression of house fly breeding in municipal refuse dumps, and to the American method of utilizing hydrocyanic gas for the destruction of house flies. Attention is drawn to the way, described as little short of scandalous, in which pastrycooks' wares in Great Britain are frequently exposed to contamination by house flies.

Under the long title *Die Lagerung Verletzter und Erkrankter Gliedmassen, Leerschienen und Verbandlose Wundbehandlung*,⁶ Dr. HEINRICH BRAUN of Zwickau (Saxony) gives a short account of the uses of his skeleton splints, which he found valuable in the war and in the years of peace which have followed. He claims good results for his open method of wound treatment, and says that his splints and their use are so simple that any practitioner should succeed in treating fractures with them.

Once upon a time Dr. WIRTH KNUDSEN, then a young graduate in political economy, was asked by a Japanese: "Why do you European men treat and regard your women with such respect, often amounting to adoration?" For twenty years Dr. Wirth Knudsen has sought an answer to this question, and at length he has found it in the legend of Don Juan. This legend, he says, is the myth of the white man's pilgrimage of pain in search of a woman who is his peer in spirit and in truth. Having concentrated to himself the idealistic needs of the whole white race, Don Juan sought to find and possess them all concentrated in one woman. He was the incarnate monogamist, driven on by each fresh disappointment until he had been compelled to love hundreds of women. In support of this view Dr. Wirth Knudsen has written *Feminism: A Sociological Study of the Woman Question from Ancient Times to the Present Day*.⁷ He is not, perhaps, so crudely violent as Mr. Ludovic on the exposition of his thesis, but it is permissible to doubt whether, in the present position of the woman question, it is any longer worth while uttering these Cassandra-like prophecies. The feminist movement has reached the stage when there is little left except to watch the effect of the experiment upon white civilization. Possibly it is not yet clear what is the exact nature of the higher and fuller

³ *Man and Sunlight*. By Hans Surén. Authorized translation from the sixty-seventh edition by David Arthur Jones, M.C. With foreword by G. W. Saleeby, M.D. Slough: The Solar Publishing Company, 1928. (Post 8vo pp. x+196, illustrated 6s. net).

⁴ *L'Année Obstétricale (Travaux de 1925)*. Par H. Vignes et B. Jean Avec la collaboration de V. Robin. Paris: Masson et Cie, 1927. (Med. 8vo pp. 288, 40 fr. sans majoration).

⁵ *The House Fly: Its Life History, Importance as a Disease Carrier, and Practical Measures for its Suppression*. By Major E. E. Austen. D.S.O. Third edition. British Museum (Natural History). Economic Series No. 11. London: British Museum (Natural History), Edinburgh: Oliver and Boyd, 1928. (8½ x 8½ pp. 71, 1s.).

⁶ *Die Lagerung Verletzter und Erkrankter Gliedmassen, Leerschienen und Verbandlose Wundbehandlung*. Von Geh. Med. Rat Professor Dr. Heinrich Braun, Leipzig. J. A. Barth, 1928. (Med. 8vo pp. 118, 101 figures, M.12).

⁷ *Feminism: A Sociological Study of the Woman Question*. By R. A. Wirth-Knudsen. Translated from the Danish by Arthur G. Chater. London: Constable and Co. Ltd., 1928. (5 x 8½ pp. vii + 332, 12s. net).

life which is to result from slaking off the domination of man. Even Dr. Wieth Knudsen does not seem to have obtained an answer to this problem.

The Art of Flying,¹³ by Captain NORMAN MACMILLAN, is full of interesting and useful information about the effects of high altitudes, aerobatics, and speed on aeroplane pilots. There is a chapter on "The sense of hearing" and another on "The human factor" which will be of real value to medical officers of the Royal Air Force and to members of the profession who may be consulted by persons desirous of taking up flying as a career. The book is well illustrated, and without being technical is a complete textbook on how to fly. In this book the statements of chief interest to those interested in the physiology of flying are that inability to hear correctly is often the initial cause of many flying accidents, that the sensations received from the pilot's seat are of great importance, that vision is affected by high altitudes, and that fainting during aerobatics occurs when the centrifugal force reaches eight times gravity. We note also the author's remark, presumably based on personal experience, that if one has a bad cold and wraps up warmly in flight at 10,000 feet for twenty minutes has very beneficial effects.

Miss E. MARY HEFTER has translated into English Professor VIGAND's textbook of *Practical Serology*¹⁴ and in an editorial preface Dr. C. G. L. Wolf commends it for its lucidity and comprehensive outlook. Professor Vignand has prepared a simple practical account of the various methods used in serology generally, and the book gives a large amount of useful information compressed into a small space. The illustrations are good and there is a glossarial index to interpret the rather formidable immunological vocabulary.

Dr. HANS SCHEFFLER of Bochum (Westphalia) gives in his observations and results of five years' fracture treatment,¹⁵ his experience as a surgeon to a coal mine which will interest other surgeons similarly employed as well as practitioners generally. The tetrapod walking sticks—if we may so call them—shown in Fig. 1 strike us as having a practical value in the early ambulant treatment of fractures.

¹³ *The Art of Flying*, by Captain Norman Macmillan M.C. A.F.C. With a foreword by Sir Sefton Brancker K.C.B. A.F.C. London: Duckworth, 1928. (Cr. 8vo pp. 159, illustrated, 5s. net.)

¹⁴ *Practical Serology*, by Luig. Vignand. Translated by E. Mary Hefter. Edited by C. G. L. Wolf. Cambridge: W. Hefter and Sons Ltd. 1928. (Demy 8vo pp. x + 221, 39 figures, 4 plates, 12s. 6d. net.)

¹⁵ *Beobachtungen und Ergebnisse bei einer fünfjährigen Frakturbehandlung* von Dr. Hans Scheffler. Berlin: J. Springer, 1927. (Sup. roy. 8vo pp. 85, 18 figures, R.M.S.)

PREPARATIONS AND APPLIANCES

A CONTAINER FOR RADIUM NEEDLES

DR. P. CLENNELL FENWICK (officer in charge of the Radium and Deep Therapy Department, North Canterbury Hospital, Christchurch, New Zealand) writes: I send a description of a very satisfactory appliance made by my chief assistant Mr. Charles Hines. It is a device for containing radium needles, threaded ready for use and during sterilization. The trouble I always find when taking radium needles to the theatre is that, when sterilized, the threads attached to each needle become entangled and much time and patience is wasted disentangling them. Two blocks of brass 3.8 in. thick are joined by strips of brass 3/8 in. thick and 15 in. in length. One is drilled on its outer edge with a number of holes which admit the needles, which fit in and leave their ends protruding. Another block is drilled through on its face with an equal number of holes. The needle is threaded and dropped into the hole in the second block, the thread is passed over the face of this block and through the hole in the other block, and then tied tight. The needles thus secured may be kept safely and conveniently until required for use. The whole apparatus can then be placed in the sterilizer. Each needle is released individually by a snip of the scissors across the string close to the block. Any needles not required are left in the frame, and thus the danger of any loss is avoided.

A GASTRO ENTEROSTOMY CLAMP

Mr. C. A. Wells (honorary assistant surgeon to the Royal Southern Hospital, Liverpool) sends a description of a gastro enterostomy clamp which has been made for him by Messrs. Thackray, Park Street, Leeds. He writes: The instrument consists of two rigid blades, one is mounted on a leaf spring the centre of which is attached to a cranked arm which occupies the position of the second blade in the ordinary clamp. When the instrument is racked up the sprung blade is approxi-

mated to the fixed blade by a force applied to its centre, thus the pressure is evenly distributed from end to end, the grip is certain, and at no point is there any tendency to crush the bowel. The instrument illustrated has a blade 6½ in. long and an overall length of 12½ in. The sprung blade has, in the end

nearer to the lock a slot through which passes a post attached to the fixed blade to give lateral stability. For cleaning purposes the various component parts are detachable. In practice the clamp is extremely reliable in its hold, provides excellent haemostasis, and does not crush.

DIRECT STEREOSCOPIC X-RAY EXAMINATION

Some pioneers in X-ray work, notably the late Sir James Mackenzie Davidson recognized very soon after these rays were discovered that a stereoscopic method of examining the shadows was very desirable. Mackenzie Davidson himself produced an apparatus, which was shown at a Royal Society conversation for viewing stereoscopically the image on the fluorescent screen. This depended upon the alternating illumination of two tubes together with the synchronized movement of a collapsing or rotating shutter so adjusted that one eye of the observer could see only the shadow cast on the screen by the first tube and the other eye only the shadow cast by the second, each eye thus saw its own image and the combination gave the stereoscopic picture. There were many mechanical difficulties in carrying out this method which prevented it from coming into use, but the correctness of the principle as well as the realism of the stereoscopic picture and its immense aid to diagnosis have always been acknowledged. Now at length a stereoscopic installation with these difficulties overcome has been constructed. It was first demonstrated by its inventor Mr. F. E. Bornhardt, at the Medical Congress at Wiesbaden last year. One such installation has been set up in London at the offices of Stereoscopic X-Rays Limited (67A Baker Street, W.1) where a representative of the *Journal* had the opportunity of witnessing a demonstration. The apparatus necessarily a large and elaborate one produces on the fluorescent screen with the minimum of adjustment and with no doubt a shadow picture in perfect relief. Two metal tubes supplied with high tension alternating current are placed side by side in a special screened receptacle the distance between them corresponding to the pupillary measurement of the observer. The tubes are fitted to a projecting arm at the back of a movable counter balanced table stand while a similar arm at the front of the stand carries a synchronized viewing device very much like the eyepiece of an ordinary stereoscope. Before this eyepiece the observer sits and watches the image on the screen, the patient standing behind the screen and in front of the supporting table. The two tubes are switched on automatically in turn, one half phase of the alternating current passing through each. Thus in using a 50-cycle alternating current there appears on the screen a shadow picture from each tube in reciprocal succession at each fifteenth of a second. The combination of the images depends on the viewing mechanism which contains rotating screens working in synchronism with the tubes in such a way that each eye of the observer can see only one of the shadow pictures at a time. The two pictures on the screen are thus optically separated but so rapid is the movement that to the eye a perfect stereoscopic image is presented. Optical correctness is obtained whether the observer wishes to have a near or distant view and by an ingenious device on the main stand considerable lateral as well as vertical movement is possible, so that the patient can be thoroughly examined sitting or standing. In depth and perspective the view obtained is everything that can be desired. The eye appreciates the spatial relation of the shadows just as it would the planes in a landscape. The value of such a facility for the study of conditions in the chest or abdomen or in any part of the body needs no emphasizing. Stereoscopic X-Rays Limited invite medical practitioners to witness a demonstration of the apparatus at their showroom, where also cases can be examined.

ABDOMINAL SUPPORTS

We have received from Messrs. H. E. Curtis and Son Limited (7 Mandeville Place, W.) a copy of their new illustrated catalogue containing particulars of abdominal supports, belts, and corsets. A glance through the pages detailing the different models and grades designed to suit as far as possible every individual requirement shows to how fine an art the making of such appliances has been carried. Directions are given for self measurement where it is not possible for the firm as they prefer to do this themselves. There are suggestions also for the wearer of the support with a view to adding to the comfort and usefulness of the fitting. The catalogue illustrates many kinds of trusses and colostomy appliances and of elastic hosiery in which every garment is knitted in one piece with an elastic spiral interwoven on the principle of the puttee so that the limb receives an even pressure throughout. The purpose of all these mechanisms is to provide an efficient and comfortable appliance which will allow the wearer to have a normal carriage and appearance.

THE IMPORTANCE OF ZOOLOGY TO MEDICAL SCIENCE*

BY

WILLIAM COLIN MACKENZIE, M.D.,

PROFESSOR OF COMPARATIVE ANATOMY AND DIRECTOR OF THE NATIONAL MUSEUM OF AUSTRALIAN ZOOLOGY

DURING the past century the problem of human development has overshadowed all others in biology, round the question of human origin a great battle has waged. Zoologists, physicians, geologists, and theologians have entered the arena, but to-day from the conflict three great names emerge—namely, John Hunter, medical practitioner and founder of the Hunterian Museum at the Royal College of Surgeons of England, Jean Lamarck, comparative anatomist, the centenary of whose tragic death will be commemorated in Paris next year, and Charles Darwin, naturalist. Hunter and Lamarck based their principles on function, while Darwin was primarily a structural biologist.

What to-day do the problems studied by these great scientists mean to the man in the street regarding himself as healthy, to the sick person seeking hospital admission for treatment of his disease, or to the mother of the paralysed child faced with a lifelong crippledom? Our ultimate judgement on these problems, regarded unfortunately by many as purely academic, depends on their relation to bodily health and disease. It is to this aspect that I particularly wish to direct attention.

STRUCTURE AND FUNCTION

It is undeniable that in the past too much attention has been paid to structure and too little to function, on which structure depends, and of which it is the register. As Sir Berkeley Moynihan, the President of the Royal College of Surgeons, said last year at King's College Hospital Medical School:

At the time when I became a medical student forty-four years ago to-day we were taught anatomy as we should be taught the plan of a city learning the names of houses, of main streets of then branches and turnings. But to the people who lived in the city their industries their way of life the part they filled in the community we were hardly expected to give a thought. For all we know the city might be dead.

An explanation is to be found partly in the influence of Sir Richard Owen, who, having studied at the Jardin des Plantes under Cuvier, the bitter foe of Lamarck, subsequently became the curator of the museum housed in the College of which Sir Berkeley Moynihan is the distinguished president, partly in the doctrine of a chance spontaneous congenital variation commonly called "sport" associated with the principles of natural selection, and partly as the result of the introduction of antiseptic surgery—the evil accompanying the good, as is found everywhere throughout nature.

Much consideration in recent times has been given to the demonstration of prehistoric skulls in an endeavour to fill the gap between the anthropoid and man. To-day no one will deny that the positive evidence in this direction now accumulated is overwhelming. But just as we have prehistoric skulls, so also have we prehistoric brains, which show side by side with the modern characteristics primitive features. The man becoming inebriated, the patient passing under the influence of chloroform, the child losing the use of its muscles through infantile paralysis—these all illustrate the functional history of human development. Only along developmental lines can a true interpretation of human conduct be made. The human body is a complex machine, made up of entities, and these have a functional history. A study of the human body, whether from the point of view of health or disease, must include these factors, otherwise it is comparable with the study of a cathedral by an architectural student unacquainted with the principles of construction of a two-roomed house. The humble cottage affords the clue to the architecture of the majestic cathedral and the reason for

the use of the different parts. It cannot be too strongly emphasized that no country in the world offers such a field (unfortunately fast disappearing) for the study of the human body as Australia. Its lung-fish, reptiles, monotremes, and marsupials represent a living embryology—an embryology different from that of the human body, for not only can structure be studied, but also function as well.

THE LOWEST AND HIGHEST MAMMALS—A CONTRAST

If in the study of function and structure we make a commencement with such a primitive type as the lowest mammal, the platypus, an animal corresponding to life on this planet a eons ago, and in which we see the genesis of the use of limbs not only for propulsion as in the lizard, but for support as well, we find little difference from a physiological point of view between the monotremes and man. The general structural scheme is similar in both. Each has a four-chambered heart, diaphragm, lungs localized to the chest, and the grey matter of the brain in both, unlike that of the reptile, is external to the white matter. Microscopically, we find that the organs of the platypus resemble those of man. What, then, constitutes the essential difference? It is really a postural one. We have the erect posture, the platypus has not. The principle we have to recognize is that the great advance from the reptiles through the mammals up to man is one in muscular action. The advantages, intellectual and other-wise, which the erect posture confers are actually dependent on this, to this everything would appear to be secondary. In the blue-tongued lizard (*Tiliqua scincoides*) we see progression on the belly wall, the four limbs being used for propulsion only. In the echidna we have an animal with its abdominal wall off the ground, and the four limbs used for bodily support as well as for bodily progression. In the kangaroo we find an interesting experiment, that animal having the erect posture by means of a tripod formed by the long feet and tail. In the orang, chimpanzee, and gorilla we find—thanks to an improved musculature at the hip-joint (the centre of motion of the body) and at the knee as indicated by strong patellar development—successive stages in which without the use of a tail there is lessened use of the fore limbs for support. Finally, in man we have the lower or hind limbs only used for propulsion and support, leaving the fore or upper limbs not merely hanging appendages, but structures free to obey the will of the higher brain, and capable of themselves being raised against gravity when the body is erect.

THE HUMAN ERECT POSTURE

Of all mammals man, the most intellectual, is the most erect. Erect man alone possesses the prefrontal brain, associated with which is the development of the characteristically human forehead. In the lower prehistoric type, as evidenced by the Columbian skull, this characteristic forehead development is absent. On the erect posture depend human intelligence. This posture is not a matter of equilibrium, for, as we know, the vertebral column is not the axis of the human body. It is maintained and effected by muscular action, and is actually dependent on the improved functional development, along the vertebrate series, of the extending muscles of the hip and knee joints—the strength of the latter being aided by the patellar development. If we compare the skeleton of the living anthropoids and man, we find that the patella, or knee-cap, gives us an index of the degree of erect posture and intellectual development. The patella of modern man is the best developed, and between the patella of the gorilla and that of the Australian aborigine would be the types represented by prehistoric man. A child that has lost the power of these two extending muscles from infantile paralysis, although the brain be unaffected, is unable to stand—becoming quadrupedal. The living anthropoids are regarded by many as mammals arising from a stem common to both us and them; they developed physically, we intellectually.

But it is unscientific to speak of the anthropoid as a specialized muscular type. If we regard it from the point of view of chest, neck, and upper limb development then it is, compared with man, a more muscular type, but if

* Presidential address delivered at Hobart before the Section of Zoology at the Australasian Congress for the Advancement of Science 1928.

we regard the comparison from the point of view of muscles supporting the body erect, such as those of the hip, knee, and calf, then it is an inferior type to ourselves. The living anthropoids simply represent failures to become erect, but as all human types, whether physically or intellectually, are not alike, so also among the early anthropoids there was one type in which, as the result of environment, the urge to become erect was marked. Little by little, over long periods of time, with bent body, sagging knees, and the lower limbs abducted to give a broad base, just as we see in an infant during the first two years of life, the effort was maintained by the prehistoric types we know to-day, resulting finally in the erect posture of modern man. Thus was accomplished the effort of throwing the body, unaided by a tail, from the quadrupedal to the bipedal stage. The whole of these facts were known to Lamarck. He knew that the erect posture was the ultimate goal, and also—that many scientists are only now learning—that the means were muscular. The common ancestors, the prehistoric types about which we hear so much to-day, were postulated by Lamarck over a century ago. He wrote, speaking of our prehistoric ancestors:

"If these same individuals were to give up using their jaws for biting, tearing and grasping, or as nippers for cutting grass and feeding on it and if they were to use them only for mastication, there is again no doubt that their facial angle would become larger than their snout would shorten more and more, and that finally it would be entirely effaced, so that their incisor teeth would become vertical."

He knew the advantages of the erect posture and its instability, but we go further. Just as it was a struggle for the quadrumanous to become humanous and finally erect, so also was it a struggle to the quadrupedal from the stage when the vertebrate crawled on its belly wall, and used its limbs for bodily propulsion only and not for bodily support. To-day the actual animals on the direct line are few (collaterals are numerous), but a definite sequence of animals possessing the necessary correlations for the ultimate erect posture—for example, muscular and intestinal—can be demonstrated. This I have termed the law of mammalian development. As regards these correlations, the retention, for example, of a hand with opposable pollex and foot with opposable hallux would be essential. In Australia we have in sequence the blue-tongued lizard (*Tiliqua scincoides*), the bearded lizard (*Amphibolurus barbatus*), and the common phalanger or opossum (*Trichosurus*). Then from the rodent series we pass on to the lemur, platyrrhine or New World monkeys, catarrhine or Old World monkeys, anthropoids, prehistoric man, Australian aborigine, and the modern European. By means of these can be traced a definite sequence in nervous, muscular, and intellectual development. From the point of view of comparative study I regard the common Australian phalanger (*Trichosurus*) as a key mammal, its intestinal tract gives the clue to the complex human arrangement. The two Australian monotremes—platypus and echidna—are not actually on the line of human development, though showing us the relationship between reptiles, birds, and mammals, they are collaterals, highly specialized, and so have remained. They have sacrificed vital structures which can never be regained. Similarly the kangaroo is not on the direct line, being precluded by the absence of opposable thumb, atrophied upper limb, and the long narrow foot—apart from other specializations, nevertheless, it affords a remarkable attempt on the part of Nature to achieve the erect posture by means of a tripod.

ADVANTAGES OF THE ERECT POSTURE

The immediate advantage of the erect posture, for example, to primitive man would be in defence against or attack on enemies. The stump-tailed lizard (*Trachysaurus rugosus*), crawling on its belly wall, lives within a limited horizon. It may be attacked from the air or behind. With the erect posture the horizon is extended. There is a view for miles in every direction, objects are seen at a distance. Vision and hearing are improved, memory arises—and memory precedes intelligence. With the erect

posture our primitive ancestors could easily signal to one another, and speech, which is a characteristic of erect man, was evolved in its simplest form—the child stands and walks before it talks.

With the hands free weapons for attack were fashioned and used, and the tactile sense was improved. It is a fact, with which orthopaedic nurses are conversant, that children, paralysed in the trunk and lower limbs and unable to walk, show an almost immediate improvement in mental outlook when placed in the erect position either by mechanical or operative means.

THE INSTABILITY OF THE ERECT POSTURE

As scientists refer to man as *Homo erectus*, we are apt to think of the erect posture as a power old and permanent. On the contrary, it is a power but recently acquired, and in Borneo, within a few days' steam from Australia, lives the orang, differing primarily from the human type in the undeveloped function of muscles which extend the hip and knee joints. At its present stage the posture is unstable, and a period of three years is spent by the human infant in acquiring balance. The stage has not yet been reached when the child can stand and walk shortly after birth. The medical practitioner dealing with nervous or muscular diseases recognizes its experimental nature, and hence vulnerability to attack, especially during the early years of life. If we consider for a moment we realize how little of our time is really spent in the erect attitude. We spend as much of the day as possible sitting or reclining, and, when standing, we seek relief from the efforts the erect posture demands in supporting ourselves by any convenient object, nor can we regard the time spent by the human race to-day in the motor car as conducive to improvement in muscular function. It is worth remembering that the primary functions of the upper or fore limbs were body propulsion and body support, and that the biological price of disuse is atrophy. The great variation in the lengths of upper limbs is noteworthy.

As I mentioned previously, the instability of the erect posture was well known to Lamarck. Let me again quote from his *Philosophy of Zoology*. He writes:

"No doubt the erect posture attitude is alien to the orang since it adopts it less when moving about and its organization is hence less adapted to it, but does it follow that because the erect posture is easy to man it is therefore natural to him? Although a long series of generations has confirmed the habit of moving about in an upright position yet this attitude is none the less a tiring condition in which man can only remain for a limited period by means of the contraction of some of his muscles, the erect position is a tiring one for man instead of being a state of rest."

With these pregnant remarks did the great Frenchman anticipate the principles governing the treatment of 80 per cent of wounded men in the great war. They were the victims of injury to muscle, nerve, and bone, and for them scientific rest and re-education were indicated.

A GENERALIZATION FOR HEALTH AND DISEASE

Throughout the Commonwealth of Australia to-day we find that hospital wards for medical and surgical treatment are everywhere on the increase, yet they seem unable to cope with the chronic patients who constitute the great problem in present-day hospital practice. With a perfect environment and so much attention paid to the so-called essentials—air, food, and water—why should this be? In spite of our hospitals, drugs, and preventive measures, it would seem that as old diseases disappear, or tend to lose their virulence, new ones take their place. Too much emphasis has been given to the attacker and too little to the attacked. Since human development has been on physiological and not on pathological lines, to obtain a knowledge of the factors that constitute health, as contrasted with disease, we must know the history of human development. This can only be obtained by a study of Nature's own experiments, only along these lines can a problem of cell multiplication, such as cancer, be attacked.

The great muscular epochs resulting in the erect posture and its accompanying superior intellectual development have affected every system of the body. Even the lizards of Australia are immediately divided into two great divisions,

one represented by the blue tongued variety (*Tiliqua scincoides*), and the other, in which we see the attempt to use the limbs and long tail for support, by the bearded (*Amphibolurus barbatus*) and the frilled (*Chlamydosaurus kingi*) lizards.

Underlying so many apparently dissimilar phenomena is the really one great fundamental basis, that with the alterations in posture produced by the muscular system every other system in the body is correlated. As new functions of intelligence arise, necessitating brain enlargement, so also must the abdominal organs be hitched to the dorsal wall to prevent strangulation. The heart must accommodate itself to the altered posture, having to pump blood not horizontally, but upwards against gravitation. The treatment of cardiac disease should consider the history of the acquisition of cardiac muscle function. Cell function is a compound of entities. Those last acquired are most vulnerable to attack and most difficult to regain, and when, for example, we speak of failure in action of muscle, liver cell, or heart, we have to determine whether the loss is of some or all the entities. Thus, in the case of the loss of function of the extending muscle of the knee, is it a loss of all the entities necessary for the erect posture, or has it retained the function necessary for use in the lowest mammal, the platypus? This principle is the basis of the now universally accepted muscle re-education treatment in infantile paralysis and neuromuscular diseases and injuries, and was evolved in Australia from researches on its unique fauna. Numerous operations for displacement of the human uterus, on which so much ill health depends, are in use. This only shows how necessary it is for the gynaecologist to recognize the history of uterine support. Only along comparative lines involving a study of birth through the Australian reptiles, monotremes, and marsupials can midwifery be raised from an art to a science. The bandicoot, a marsupial mammal of the greatest importance for placental study, is now almost unobtainable.

To-day we see the apotheosis of muscular development, but it is essential that physical culture should follow the lines along which the erect-posture has been acquired, and be directed towards helping those muscles on which it particularly depends. To develop a sound muscular system we must not only have rational exercise, but rational rest as well. Such exercising as golfing, tennis, or long walks may, to the city man engaged in mental activities, act as an irritant, since more often muscular repose is indicated. The cause of dullness in the school child may be the result of faulty seating accommodation. The child is compelled to sit erect on seats without backs, and is forbidden to rest the head on the hands, with the result that mental effort is expended not only on lessons, but on balance as well. How often is our enjoyment of a play or lecture spoilt through a similar cause! Do we realize how the output of a factory can be lessened through faulty posture? The laziness of the Australian aboriginal has a physiological basis, with his long arm and poorly developed lower limbs he is nearer than we to those prehistoric types who walked with bent neck and with sagging knees.

Probably no game in the world, not even excluding tennis, exercises the erect posture functions more than the Australian game of football. It is founded on sound physiological lines and has been a no small factor in the physical development of our nation.

In conclusion, if we exclude specific infectious diseases which are in the main preventable and due to segregation, we may define health as a correlation of all the bodily systems to the erect posture, and ill health as a failure of one or more systems to correlate to it. In any case of chronic ill health an analysis of the postural system should precede all other investigations.

In the hospital of the future a primary consideration in treatment should be given to Nature's methods. We are intent on surgical wards, theatrics, and equipment, but an essential in any public hospital is a great department of myology wherein a scientific examination can be made for muscular defects, and their importance assessed.

Nova et Vetera.

THE CHINESE DOCTOR

THE Chinese quack has been so written up and has become so well known that the Chinese doctor has been eclipsed, some notes about him may therefore be of general interest. The medical student is usually trained by being apprenticed to a man in practice, he has an extensive literature to study and a vast pharmacopoeia to employ. Some eventually gain a very high reputation, and are trusted by their patients. I have come to know several, and will mention some of their cases which have come within my ken.

Tobar Pneumonia—This is well known as such to Chinese doctors. A woman in my hospital had a patch that would not clear up, she also had fatty heart. I sent for the woman's family physician, who lived thirty miles away, he was quite ignorant of Western methods and had never seen a stethoscope, but he told me, after going into the whole case with the patient, that she was weak inside and strong outside, which was his way of saying fatty heart, and that she had been insufficiently stimulated during a recent pneumonia. I asked, "Is there pus?" He said, "Not yet, but a needle would do no harm." I tapped for pus and drew only blood. He gave her three prescriptions and the patient rapidly recovered. He felt the pulse most carefully and went into the history minutely. The methods were seemingly crude, but his deductions were correct and his treatment was effective.

Enlarged Spleen—A man had been tapped twice and sent home as the spleen reached the umbilicus (I do not know the cause of the enlargement). He went home and bought his coffin, but a friend suggested that arsenic pills should be taken increasing by one daily up to twenty six and then diminishing daily by one. I saw him after this course of treatment, and the spleen could only just be felt under the rib.

Pulmonary Tuberculosis—A very advanced case of tuberculous lung was successfully treated by a Chinese doctor expert in physical culture by graduated exercises and drugs, the patient living for many years subsequently. At the time he was so ill that the father had to kowtow and beg the doctor to undertake the case before he would consent, as it seemed hopeless.

Anthrax is common. A boy, aged 8, was brought to hospital with a sore on the upper lip and a temperature of 101° F., he had fainted twice on the road while being carried. The microscope verified the diagnosis. I was very "sachcheerful," but a Chinese assistant said to me aside, that he had an uncle, an anthrax specialist, and he himself knew the treatment, so we treated the boy by stewing three herbs, using the stewed leaves as a poultice, while the infusion was drunk. The lad went home perfectly recovered on the fifth day. The herbs were verbeena, sorrel, *Carpesium abrotanoides*, and enough rhubarb root to keep the bowels acting. These herbs are very common in that locality, I had them identified at Kew. That summer we treated six bad cases of anthrax, one patient had a face swelled beyond all recognition.

Stroke—I spent two hours in a sedan chair reading up in a copy of the *British Medical Journal* an illuminating article on stroke, and arrived at the patient's house well primed in the differences between cerebral thrombosis and apoplexy. The patient, aged 35, had kala azar, and had been going the pace, so I concluded it was thrombosis causing left-sided hemiplegia. An old country Chinese doctor, who was there and knew the condition, said that purgatives must be avoided as it was the weak variety of stroke—his way of saying that it was cerebral thrombosis and not cerebral haemorrhage.

These doctors are much respected when they have acquired their reputation, and I think they deserve respect from Westerners. To class Chinese doctors and quacks together, and ridicule them all, makes enemies. By cultivating friendly relations with the native doctors we shall learn some of their secrets, which are of real worth. Livingstone, though he lived among very primitive people, always treated the native doctors with respect, and so won their friendship. In surgery, of course, we are supreme, and they know it, they have no anaesthetics and no antiseptics. Rockefeller has seen the value of a friendly gesture, and has contributed lavishly to found in Peking a first-class hospital. During the recent upset in China the Americans have escaped the systematic boycott which

has inflicted heavy financial losses on the British. A friendly gesture at this period, when the Yangtze valley is emerging from the Russian nightmare, would be of untold value as estimated in hard cash. A really good hospital built in Hankow by the great trading concerns would pay for itself over and over again. The Asiatic Petroleum Company, the Anglo-American Tobacco Company, the cotton industry—these three alone could easily erect a first-rate hospital. The ground is well prepared by the wonderful opinion the Chinese have of Western surgery. Half a million so invested would repay itself by creating a friendly atmosphere, no other form of philanthropy would do this so well.

RECENT ADVANCES IN THE CHEMOTHERAPY OF SYPHILIS

CAMERON LECTURE BY DR. LEVADITI

The following is an abstract of the Cameron Prize Lecture given at the University of Edinburgh this summer by Dr. O. Levaditi of the Pasteur Institute, Paris. The title of the lecture was "Recent advances in the chemotherapy of syphilis."

Bismuth Therapy

The pharmacological action of bismuth was studied by Balzer in 1889, but Santon and Robert (1916) were the first to demonstrate its spirochaetocidal action in fowls infected with *S. gallinarum*. Levaditi and Sazeac (1922) showed that intramuscular injections of bismuth cured syphilitic lesions in rabbits, and these authors, with Tourner and Guenot (1922), applied this method to the cure of human syphilis. It is interesting to note that the therapeutic dose for a man weighing 60 kilograms was found to be as low as the maximum dose tolerated by a rabbit weighing 1 kilogram, whilst three times this dose was found to produce toxic effects in man.

Bismuth salts show a relatively high toxic action when administered intravenously, and therefore it is best to administer them intramuscularly. Bismuth administration produces satisfactory results in syphilis, both as regards its clinical effects and also as regards its effect in rendering the syphilis serum reactions negative.

The durability of the effects produced is a striking feature of bismuth treatment, for relapses are relatively rare. This is probably due to the tendency of bismuth to form depots in the body. Bismuth will sometimes produce a curative action in cases that are resistant to arsenic therapy. The completeness of the curative action is proved by the occurrence of cases of reinfection after bismuth treatment (Gougerot).

Bismuth is slowly absorbed from the site of injection, but is excreted even more slowly, and storage occurs chiefly in the kidneys, but also in the liver. Bismuth becomes activated during the process of absorption from the site of injection. Levaditi and Yamanouchi (1908) showed that atoxyl had no action on trypanosomes *in vitro*, but that it was activated by the organism, and a substance—trypanotoxyl—was formed which was an active spirochaetocidal agent. In the same way bismuth is activated by the body tissues (in particular by the liver), with the formation of an active product bismoxyl. This is a protein compound of bismuth.

The power of tissues to transform bismuth salts to bismoxyl appears to be proportional to their content in glutathione. Kolle (1924) advanced the theory that bismuth does not destroy *Treponema pallidum*, but that it cures the syphilitic lesion by promoting tissue reactions and general immunity reactions. Levaditi and Sanchis Bavaria (1927) showed, however, that in experimental syphilis in rabbits bismuth caused a rapid destruction of the parasites. The popliteal glands of infected animals were found to be non-infectious after bismuth treatment. This is a very severe test of the completeness of sterilization. The amount of bismuth that reaches the sites of infection is extremely small—only a few micrograms.

Bismuth probably acts as a catalyst, causing an increase in the defensive reactions of the body.

The therapeutic action of bismuth is proportional to the quantity of activated bismuth circulating in the body. This quantity is indicated by the tissue content of bismuth—tissue metallic potential (Levaditi and Manin). This factor is higher with insoluble bismuth salts than with metallo bismuth. Recent experiments with camphor-carbonate of bismuth, which is an oil soluble compound, have shown this to be very efficacious.

Spirochaetocidal Action of Metals

Levaditi and his co-workers have tested *in vivo* the spirochaetocidal action of forty-five metals. Of all these, only eight were found to be active—namely, arsenic, gold, mercury, bismuth, vanadium, ruthenium, platinum, and tellurium.

Tellurium shows a remarkable curative action both in human and in experimental syphilis (Levaditi and Manin). Unfortunately its use is limited by the fact that it forms methyl tellurium, which is excreted by the lungs and imparts a strong garlic odour to the breath. This odour may persist for months after a single dose. Tellurium causes also blanching of the hair and pigmentation of the skin. Vanadium is somewhat less active than bismuth. Gold is fairly active, and has been used in human syphilis in the form of gold and sodium thiosulphate. Unfortunately it has a relatively strong toxic action.

A consideration of the positions in Mendelejew's table of the eight active metals fails to show any significant common factor. These eight elements, however, all fall into the same group of atoms when the atoms are classified according to their electro-chemical properties (Levaditi and Longuesco). All metals showing a therapeutic action are either very feebly electro-positive or very feebly electro-negative. Their polarization tension is generally lower than that of hydrogen, and they do not decompose water at room temperature. From the analytical point of view, they all are precipitated by H₂S as sulphides. These would appear as necessary conditions for an element to be active. The formation in the tissues of proto-metallic spirilloidal compounds (bismoxyl, trypanotoxyl) depends on these conditions (Levaditi). The fulfilment of these conditions is not, however, sufficient to ensure a spirochaetocidal action, since some metals, such as copper and palladium possess these properties, but, as far as is known, have no action on spirochaetes.

ROYAL MEDICAL BENEVOLENT FUND

At the last meeting of the committee fifty applications for assistance were considered, and £225 was voted to 45 cases. Consideration of the following notes will show how sad some of the cases are and how urgent is the need of help. Unfortunately the grants were small, and the Fund appeals for subscriptions to enable it to give more adequate amounts. Subscriptions and donations should be sent to the Honorary Treasurer, 11 Chandos Street, Cavendish Square, W.1. Among recent cases were the following:

L.R.C.S. Ed. aged 74 and wife aged 72. The husband is quite unfit to do any kind of work. Their total income is £82 a year (made up of old age pension £52, and Epsom pension £30) and their rent is £26 leaving only £56 for food and clothes. Voted £40 raising their income to £122 a year.

M.D. aged 75, bedridden and has no private means but was able to earn a little last year from literary work. Voted £40.

Widow aged 73 of L.R.C.P. On the death of her husband in 1923 her house was sold the proceeds going to pay off existing debts leaving the widow only £370 as capital. She is in receipt of the old age pension, her relations have given her no financial assistance this year but cannot continue to do so. Voted £25.

Widow aged 62 of M.B. Since the death of her husband has supported herself and her invalid son by taking in paying guests. Owing to ill health has been unable to do so during the last twelve months. Her income during past year was £7 10s. from investments and £5 from a paying guest. Voted £126. The Fund is trying to get other charities to assist.

The Royal Medical Benevolent Fund Guild still receives many applications for clothing, especially for coats and skirts for ladies and girls holding secretarial posts, and suits for working boys. The Guild appeals for second hand clothes and household articles. The gifts should be sent to the Secretary of the Guild, 58, Great Marlborough Street, W.1.

SATURDAY, SEPTEMBER 22ND, 1928

ACUTE NEPHRITIS

THE subject of acute nephritis, with its wide bearings, was debated in the Section of Medicine of the Annual Meeting of the British Medical Association at Cardiff, and the opener of the discussion was most appropriately the Regius Professor of Physic in the great school of the University of Dublin, which has been so pre eminent in advancing clinical medicine. Professor Gillman Moorhead, in his address published in this issue at page 515, draws attention to the recent numerous additions to our knowledge, due in some measure to the prevalence during the late war of epidemic nephritis, though indeed this disease was prevalent also in the American civil war sixty years ago. There were thus provided a stimulus and opportunities for observation and for the elaboration of functional tests, among which may be mentioned those of Professor Hugh MacLennan. The choice of a discussion on renal disease is historically appropriate after last year's centenary of Richard Bright's *Reports of Medical Cases selected with a View of Illustrating the Symptoms and Cure of Diseases by a Reference to Morbid Anatomy*, a consideration which may also have weighed with Dr T Izod Bennett, an alumnus of Guy's Hospital Medical School, in making "Some problems of nephritis" the subject of his stimulating Goulstonian Lectures last March.

The prophylaxis and etiology of acute nephritis are obviously dependent upon the same fundamental question—namely, the nature of the factors responsible for the renal lesion. The onset of acute nephritis is preceded in a great majority of the cases by evidence of general or local infection, thus, for example, Longcope, O'Brien, McGuire, Hansen, and Denny (1927) found that in forty cases of acute or subacute glomerulo nephritis there was in 85 per cent a previous or concomitant acute infection, such as tonsillitis, sinusitis, broncho pneumonia, or scarlet fever, which in a large proportion was due to haemolytic streptococci. It has been widely assumed that the diffuse renal change is due to the action of toxins absorbed elsewhere rather than to the existence of micro organisms in the kidney, as occurs in the focal form of glomerulo nephritis so characteristic of subacute bacterial endocarditis, in which *Streptococcus viridans* is certainly present in the glomeruli. Longcope and his colleagues did not find any evidence that streptococci caused the glomerular lesion by direct invasion of the kidney, cultures of the blood and urine remaining sterile. But although the sequence of streptococcal infections and acute nephritis is fully admitted, it has been thought by Munk and others that the actual cause of the glomerulo nephritis still remains to be established. An interesting conception is that diffuse glomerulo-nephritis is secondary to a diffuse capillary inflammation (Schlayer, Klyn), thus really reviving

the idea embodied in F A Mahomed's description half a century ago of the pre albuminuric stage of scarlatinal nephritis, which idea also laid the foundations of Sir Clifford Allbutt's hyperpiesia. This view of acute glomerulo nephritis corresponds also with Gull and Sutton's conception of chronic granular kidney as a local result of a general arterio-capillary fibrosis. With regard to prophylactic treatment in scarlet fever, Professor Moorhead points out that in the light of Peters's observations Osman's alkaline treatment must be regarded with caution as well as with hope, similarly his experience does not lead him to support the vigorous alkaline treatment of nephritis advocated by Martin H Fischer of Cincinnati, and more recently employed by A A Osman.

The term "nephrosis," introduced by Müller and adopted by Vollhard, has been used in Germany and the United States to describe degenerative apart from inflammatory changes, associated clinically with oedema and much albuminuria, but without raised blood pressure or cardiac hypertrophy. It has not been widely adopted in this country, and Professor Moorhead, while admitting that the phrase "toxaemic kidney" describes the same condition, does not propose to employ the German equivalent, since he regards nephrosis as merely a form of acute nephritis. In the subsequent discussion Drs A E Gow and Mackenzie Walls definitely indicated that there were two types of acute nephritis—namely, a diffuse glomerulo-nephritis and a toxic degeneration of the convoluted tubules. Dr H L Tidy gave an account of acute haemorrhagic nephritis, occurring chiefly in the young and in association with tonsillitis and cervical adenitis, but without a history of scarlet fever in the majority of the cases—a condition also described two years ago by Wyllie and Moncreff. This form is benign as compared with other varieties of acute nephritis, it clears up in a few days, and in 75 per cent of the cases does not cause any permanent renal impairment. Dr Tidy, indeed, after mentioning that the only microscopic change was haemorrhage into the glomeruli, was inclined to regard it, not as a true nephritis, but as a condition of increased renal permeability. Professor Moorhead's experience, on the other hand, did not separate so sharply the haemorrhagic from the other cases.

The prognosis of cases of acute nephritis does not rest on any definite basis such as that suggested by Longcope and his colleagues. Though, in the course of their investigations, they found evidence in favour of a direct relationship analogous to that obtaining between a septic focus and arthritis, the persistence of the nephritis does not appear to depend on the continued presence of a septic focus or of an infecting micro organism. As regards treatment, Professor Moorhead, while admitting the absolute necessity for rest in the early stage and as long as haematuria continues, was not inclined to insist on its rigid continuance for lengthy periods. No special form of drug is recommended, and his trials of ammonium chloride and the diuretic novasurol, strongly advocated by the workers at the Mayo Clinic, have not engendered any enthusiasm, novasurol being much more satisfactory in cardiac than in renal oedema. Professor Moorhead then considered, but only to reject, the operation of decapsulation. In uraemic convulsions bleeding

combined with lumbar puncture has proved effective, morphine—which formerly, for some now inscrutable reason, was strictly tabooed—has proved both safe and satisfactory in checking repeated convulsions, just as it does in the allied condition of eclampsia.

BACK TO HUNTER

Why is it that the leading surgeons of to-day have cold shouldered zoology? Dr W. Cohn Mackenzie, who made his high and deserved reputation as a practising orthopaedic surgeon in Melbourne, has answered this question in an address on 'The importance of zoology to medical science' which appears in our present issue, at page 534. His explanation is that zoology as taught to-day is divorced from what is vital to medical men—the study of function. As Dr Mackenzie points out, it was not always so. John Hunter studied comparative anatomy to discover function, for Hunter, structure was "the register of function." Lamarck, who worked in the generation which succeeded Hunter, was a physiological zoologist, his contemporary, the great Cuvier, on the other hand, was not interested in function. Sir Richard Owen, who was strongly influenced by Cuvier, became enamoured with the science of Form or Morphology. Then the Darwinian period followed, when the interest of zoologists was concentrated on evolutionary problems.

Surgeons of to-day grew up on evolutionary zoology and could see nothing in it which bore in any way upon the practice of medicine. Hence their present attitude towards general zoology and comparative anatomy. It is true that in these latter days there has been a revival in knowledge of economical or applied zoology. Such knowledge has become necessary for certain branches of medicine.

Dr Mackenzie contends that zoology or biology rightly taught and studied yields the key to many medical problems. He advocates a return to the methods and outlook of Hunter and of Lamarck. This return, however, must not be made empty-handed: we must take back with us what we have learned from Lister, from Virchow, and particularly from Darwin. It was Darwin who taught us to look upon the human body as having a history. The real problems of evolution as Dr Mackenzie rightly maintains relate not to structure but to function. Man's body is a huge, wonderfully dove-tailed conglomerate of functions. If we are to study aright we must direct our attention to the order, time, and circumstance in which each item of this huge conglomerate has been acquired.

Dr Mackenzie seeks to illustrate his thesis by citing the most fundamental function of man's body—that of posture. Posture is not a matter of shape of bone or conformation of joint, but of nerve and muscle, it is the result of a complex of neuro-muscular mechanisms. Dr Mackenzie sees an early stage in the rise of the postural mechanism in the lizard of Australia, a later one in the monotremes, a peculiar specialization of it in the kangaroo, a more generalized expression in the tree opossum. The final stages which lead on to man's erect posture are to be observed amongst primate forms—in lemur, monkey, and anthropoid ape. Every animal is an experiment in posture, man's posture is the accumulated results of a long series of acquisitions. Dr Mackenzie maintains that the order of acquisition is revealed by disease: disease tends to attack the latest and then work backwards. Unless we have the key which zoology provides we cannot understand what we see.

This decline of function is not only preached by Dr Mackenzie, he practises it. He is mainly responsible for a great experiment which has been launched in Australia and which we in Britain will follow with a sympathetic interest, for it is an attempt to realize the ideal of John Hunter. When it was determined to centralize the Commonwealth Government at Canberra a scheme was sanctioned for the creation of a National Museum of Australian Zoology in the new capital. Dr Mackenzie was called upon to organize and direct this great undertaking. His lecture reveals to us the lines on which he is to proceed. The museum will be arranged on a scheme which will illustrate the manner in which animals live, move, and have their being: it will follow the plan of Hunter's museum. Animals are to be studied alive as well as dead: structure both macroscopic and microscopic is to be correlated with function. The problems relating to the maintenance of animal health, as well as the prevention and cure of disease, are to be illustrated. It is to be a research museum, ever inquiring into zoological problems with an eye which is alive to those of medicine. The care of the fauna of the whole Australian continent will be centred in the directorate of the museum: the rarer forms, many of which are threatened with extinction will be protected as well as studied. Zoology is to be a handmaid to medicine. Truly Australia has launched a great experiment.

Dr Cohn Mackenzie is a declared Lamarckian, he believes implicitly in the inheritance of 'acquired characters'. It is quite true that Lamarck has supporters in all civilized countries, his is an easy way of explaining the evolution of new structures of a purposive kind. Yet as evidence accumulates as we come to know more intimately the processes which fashion the embryo and which control and co-ordinate the vital processes of the body, the less satisfactory does Lamarck's explanation seem to be. But of Dr Mackenzie's main thesis—that function rather than structure should be our main study—there can be no question and his present advocacy of the bearing of such studies on the advance of medicine is most timely.

PSYCHOLOGY IN THE MEDICAL CURRICULUM

As recorded in our last issue (p. 498), "the place of normal psychology in the medical curriculum" is the subject of a report just published by a subcommittee of the British Association. The report points out that half the medical schools in the British Isles offer no facilities whatever for the instruction of their students in normal psychology. This is in striking contrast to the provision made in the Dominions and in the United States, where all the well-known schools offer such instruction, always on an ample, and sometimes on a lavish, scale. In those countries also the course in normal psychology is the prelude to instruction in abnormal psychology, which is taught in addition to the statutory course in mental diseases. Such a consecutive scheme is seldom found in this country, and where it is found is still more rarely compulsory. One or other of the alternatives indicated by this contrast of conditions at home and abroad must be right, either instruction in normal and abnormal psychology is needed by the future practitioner very urgently, or the necessity is slight. It is now universally admitted that a large part of every doctor's practice consists of minor conditions of a "functional" nature, in the sense that the symptoms depend primarily on the state of the patient's mind. To teach abnormal psychology—which is the knowledge of such states of mind—to students who have had no preliminary grounding in normal

psychology is like giving instruction in fractures to those who have never been taught anatomy. Nor does the statutory course in mental diseases cover more than a small part of the field of abnormal psychology, and that perhaps the least important portion for the general practitioner. The subcommittee has therefore suggested that the compulsory course in normal psychology should be followed by a similar course in abnormal psychology, which would then become part of the statutory instruction in mental diseases. In this way the student may be equipped to some extent to deal not only with definite mental illness, but with the innumerable anxious and hysterical states which masquerade so often in the guise of some physical ailment, and constitute so considerable a proportion of every practice. We are of opinion, however, that if a course in normal psychology is to be a useful prelude to such comprehensive instruction in mental pathology, it must have definite regard for medical needs, and must deal primarily with the individual as a whole and as a human being. The time-honoured accounts of association, discrimination, and the like, and what has commonly passed for a description of the emotions, must be modified to fit the facts that the student will encounter in his patients. The programme outlined by the subcommittee is an important contribution to the problem of the education not only of the practitioner, but through him of the public, for if it were adopted the public would much less often seek the services of that acute but not often profound student of human psychology, the unqualified practitioner of varying designation.

CONSERVATIVE TREATMENT OF APPENDICITIS IN A RURAL AREA

From time to time most important research is carried out with the simplest of means in country districts where the general practitioner is unable to enjoy the benefits of libraries and technical institutions, and of intimate communion with the leaders, for the time being, of the medical profession. Of the value of such communion to most men there can be no doubt. But now and then it would seem that isolation helps a mind of a certain type to escape from the stereotyped ruts into which dominating personalities are apt to force their fellow beings. In his rectorial address at St. Andrews University (1926) Fridtjof Nansen said "I tell you deliverance will not come from the rushing, noisy centres of civilization. It will come from the lonely places." Thoughts such as these come naturally to the mind on the perusal of a paper by Dr. Nicolai Nissen in the journal of the Danish Medical Association with the title "Twenty years' experience of appendicitis treated on conservative lines." Some score of years ago, and after serving for several years as a hospital intern, the author settled down in general practice with a vivid mental picture of appendices hot and appendices cold, brought to the light of day by the doctrine that operation is the sovereign remedy for appendicitis. Among the hospital memories with which he entered on general practice was that of an able-bodied young man who jumped lightly on to the operation table to have an appendix removed which had been slightly inflamed several months earlier. Sepsis supervened with fatal consequences. Having settled about four Danish miles away from the nearest large hospital, Dr. Nissen proceeded to treat his patients on the conservative lines laid down by his fellow countryman Dr. With. Thanks to the careful records which were kept he was able, after twenty years, to present rather impressive evidence in favour of his unsurgical heresy. Of his 93 cases he discarded 12, because he could not be quite sure that the diagnosis of appendicitis was correct. It should be noted, however, that all these 12 patients, who

were treated as for appendicitis, recovered. So did all the remaining 81, in whom the diagnosis of appendicitis depended on the existence of the four cardinal symptoms: pain in the abdomen, vomiting, fever, and tenderness over McBurney's point. Several of these cases, as Dr. Nissen's published records show, were very severe, but in the acute stage only 3 patients were sent to hospital, and 13 others were admitted later on to hospital for operation *a froid* because relapses had rapidly followed the first attack. For the sake of comparison Dr. Nissen publishes the appendicitis records for four years of a Danish hospital which he names Q. Here 247 cases of appendicitis were treated, 58 for chronic and 189 for acute disease. Among these cases there were 19 deaths, all after operation *a chaud*, 16 being due to general peritonitis, 2 to sepsis, and 1 to broncho-pneumonia. Dr. Nissen then paints with light but lurid touches the picture of the patient hurried off to hospital for an operation. First of all there is the psychic shock of the announcement that an operation is inevitable. "There sinks into his mind a state which the English describe as 'downhearted'—a bad companion for an operation." Then there is the Calvary of the transport to hospital, during which the patient not only becomes chilled, but also jolted, he the attendants ever so careful. "Can any doctor believe that all this can happen without a loosening of the still frail barriers formed by adhesions which prevent the escape of the infection into the peritoneal cavity?" Dr. Nissen's treatment may be simple, but it also entails scrupulous care. When he considers the case serious enough he gives an injection of morphine forthwith. In other cases tincture of opium, 10, 15, or 20 drops, is given at six hourly intervals, precisely at 6, 12, 18, and 24 o'clock. A few more drops of morphine are given if the pain has not passed off in twenty-four hours. Only water, tea, and oatmeal gruel are given, and not until the temperature has begun to become normal is milk permitted. The bed-pan is used for passing urine as well as faeces, and, to avoid disturbance of the patient by the making of his bed, a tightly stretched draw sheet is secured under the pelvis. The patient is sternly told to lie still in bed, if he must needs move a little he must do so only with his arms or left leg and it is explained to him that the diseased appendix rests on a muscle passing down to the right leg, and that if it be flexed the swollen appendix may easily be torn. Hot compresses being difficult to regulate under rural conditions of nursing, a good substitute is a warm sandbag lying along, and slightly under, the right side. These, in short, are the lines on which Dr. Nissen has achieved his unbroken record of successes, they depended, no doubt, in large degree on his personality—on his ability to impress on the patient and those around him the necessity for observing conscientiously every detail of his regime. He may not, perhaps, convince all his colleagues that he is right in his conclusion "In the country With's treatment at home is the only correct treatment for acute appendicitis." But he sets a striking example to his rural colleagues in the matter of patient and consistent observation, and he has provided matter wherewith the practitioner may console himself should geographical or other conditions prevent him from sending his patient straightway to hospital.

THE HISTORY OF HOSPITALS

SOME years ago it was not unusual to find in histories of the rise of Christianity on the ruins of paganism the statement that public charity to the sick and the establishment of hospitals were unknown before the days of Constantine the Great. A wider view of the ancient world, based on a greater knowledge of ancient society in Asia, as well as Europe and Northern Africa, has shown that hospitals for the sick were established long before the Christian era.

The Vicary Lecture on this subject delivered by Dr George Parker of Bristol, has recently been published in the *British Journal of Surgery*.¹ Dr Parker has surveyed the whole field, and as a result of his studies is able to assure us that "the earliest beginnings we know of can be traced to about the sixth century B.C., in places far apart, both in the West and distant East." It is a curious and unexplained fact that there is no evidence of the existence of hospitals in Assyria, Babylon, early Egypt, or China. In the case of Egypt their absence is hardly surprising, seeing that the time Egyptian culture had disappeared by the sixth century B.C. It is, however, surprising that China, which so readily accepted Buddhist teachings, should not have adopted the Buddhist practice of founding hospitals, yet, as far as we know, there were no hospitals in China until, in quite recent years, they were established by Christian missionaries. We confess to some surprise at Dr Parker's statement that "In England, besides monastic infirmaries 577 hospitals and asylums were founded between 1100 and 1400." As the population in 1400 is not likely to have exceeded three millions, and after the ravages of the Black Death was probably much less, this would give a ratio of one hospital or asylum to every 5,200 of population, leaving out of account the monastic infirmaries which Dr Parker excludes. No doubt many, if not most of these establishments were not hospitals in the modern sense of the word, but refuges for the sick poor, just as the existing St Bartholomew's Hospital was in its earlier days. This is a distinction which Dr Parker is careful to draw, but making, as he does, large deductions on this account the number of places for the treatment of the sick and wounded, in non-Christian as well as in Christian lands, is simply astounding. It is to Gautama and his followers that we owe, apparently, the hospital idea. Buddhist hospitals in India existed before the invasion of Alexander which, moreover, only touched the northern part of that country. The Persians early founded hospitals, and at Gondishapur we are told that there was a flourishing medical school, composed partly of Zoroastrians and partly of Nestorian Christians. In Greece, as is now well known, there were numerous institutions of the Aesculapian cult, where cures were wrought more by magic than by medicine. The more scientific Hippocratic schools do not appear to have had hospitals at their disposal, although there is not much evidence on this point. We cannot follow Dr Parker in his fascinating study of the Christian hospitals, and must content ourselves with a warm recommendation of his lecture to all who care for this interesting section of the history of medicine, nor will space allow us to do more than mention his researches into the history of Moslem hospitals, which are full of instruction for most of us.

TERMINAL DISINFECTION

When in the latter half of the nineteenth century, people came to realize that the world they lived in was thronged with invisible germs, which crowded its surfaces, swarmed in its waters, and even floated on the circumambient air, and when in addition, they were credibly informed that these same germs were the probable cause of maladies of the communicable type, they naturally enough, in their then state of knowledge, with bacteriology in its infancy, supposed that since the germs were ubiquitous, diseases threatened on every hand. Lord Lister, during the pioneer stages of his methods which transmuted the art of surgery, was inevitably influenced to some extent by the outlook of his day. Believing that wound infection came

from the air, he operated for a time in an antiseptic atmosphere under the carbolic spray. When it became clear that the wound infecting bacteria were not the casual denizens of the air, but were carried directly into wounds in the net of manipulation, the carbolic spray, having served its turn, was withdrawn from the uses of surgery. Some have thought it remarkable that the science of hygiene, which has such an intimate association with bacteriology, should have been thus outpaced by the surgical art in the application of bacteriological principles to its field of work. The practice of terminal disinfection, or the general disinfection of premises after the recovery, death, or removal to hospital of a case of infectious disease, proceeds on the assumption that the germs of the disease from which the sick person suffered are not only present on the floor or walls of the apartment in which he lay, but are in these situations a source of imminent risk of transmitting the disease to others. Such an assumption is at variance with the revealed facts of biology. Most of the pathogenic protozoa—apart from such as may survive for brief spaces in natural water, as to which there is no question here—are obligatory parasites, and cannot maintain themselves outside the vertebrate or invertebrate body. The pathogenic bacteria—apart from the pathogenic-spore-formers found in the soil—habitated in the body of man to a temperature of 37° C and a moist protected existence, lose their virulence and perish quickly in the cool arid outer world. While the patient is still present in the house the germs of his disease, passing directly to another person, have the power to infect, when he goes, the risk of infection goes with him. Once he has gone, except for such material as his bedding, which has been near his person, any live bacteria on the premises are moribund, and both the need and the opportunity for disinfection have passed. Yet the costly and laborious practice of terminal disinfection is still the firmly established routine of most public health local authorities. Here and there, and from time to time, enlightened administrators, including Dr T. F. Dewar of the Scottish Board of Health, have entered protest or counselled moderation, and for certain diseases more rational measures have begun to be adopted. The case for the abolition of needless terminal disinfection will be notably strengthened by the views expressed by Professor Carlos Chagas, the director-general of public health in Brazil, whose name is well known in connexion with the sleeping sickness of South America, of which he discovered the contagium vivum. Professor Chagas's article,¹ originally published in French, is now printed in English in a booklet with a preface by Dr Dewar. Methods for the prevention of infectious diseases, he says, ought to be essentially founded on the conviction that the sources of infection are living bodies, and not places or inanimate objects. Terminal disinfection with a view to the purification of rooms and articles contained therein is an antiquated and unjustifiable procedure. It should be replaced by simple cleansing preferably by domestic methods. If current disinfection is properly performed there will be nothing left for terminal disinfection to do. The eponymous patron of Chagas's disease, a disease which is conveyed by a bug, will probably agree that the terminal disinfection of premises in England for the destruction of insect vectors of disease is still a useful proceeding. As regards the particular subject of his article, it would appear to be the case that, on the grounds alike of economy, common sense, and scientific consistency, a general halt should be called to the exhaustive terminal disinfections now employed by public health authorities for some common infectious diseases of this country.

ABSENTEEISM IN COAL MINES

SOME eighteen months ago the Industrial Fatigue Research Board published the results of an inquiry into the relation of atmospheric conditions to the working capacity and accident rate of miners, an account of the conclusions reached appeared in our columns on February 5th, 1927 (p 246). In continuance of this line of inquiry the same workers have now completed a further study,¹ based on records of absenteeism relating to about 23,000 miners, with the object of measuring the relation of different kinds of absenteeism to various operative factors, and more particularly to depth of working and atmospheric conditions. The complexity of any problem arising from absenteeism will be at once apparent to all who have any experience of the working of national health insurance, the Board, in a preface to the report, emphasises the need for caution—which the authors, Dr H M Vernon and Mr T Bedford, admit—in accepting the conclusions remarking that the question involves not only physiological factors, but also a number of social ones. In the present case the importance of the latter factors has probably been reduced by taking a group of collieries in the same neighbourhood and apparently subject to the same social conditions. It is also pointed out that correlation between one variable and another, which was the principal test applied in the report, implies association and not necessarily causation. Nevertheless, after taking these qualifications into account, the report is an exceedingly interesting and suggestive document, the chief conclusions relating to “the extraordinary sensitiveness of the miner to his conditions of work and his general environment.” It has been found that “any and every change of condition affects, not only his voluntary absenteeism, but in addition the time lost by sickness and accidents as well.” It is suggested, therefore, in the report that the most valuable method of reducing absenteeism is to improve the conditions of work. Among factors considered were the depth of the workings and the underground temperature (which are closely related), the air velocity, the thickness of the seam, the labour turnover, and the age of the men. It was found that total absenteeism varied with the depth and mean temperature, a rise of 13° F in the dry-bulb temperature was associated with a 63 per cent increase of sickness in the coal face workers, while a rise of 10° was associated with a 74 per cent increase of sickness in the other underground men. Absenteeism from sickness and from accidents was related also to the air velocity, accident frequency rose sharply with a rise in the underground temperature, but accident severity was not much affected. The rate was considerably higher in the working of thick seams—through falls of coal being more numerous—while minor accidents varied in frequency with output and labour turnover. Accident rates were found to be closely related to the ages of the men, and to vary greatly at different hours of the shift, in men working at the coal face at high temperatures the maximum frequency was reached at the last full hour but one, while in those working at low temperatures it was not reached until the last full hour. Voluntary absenteeism increased with the distance walked underground by the men, with the distance separating the collieries from their homes, and with the labour turnover, and was also influenced by the proximity of large towns. The report, it will be seen, has opened up a wide field for investigation, presenting a series of problems of which only a few come within the sphere of the Fatigue Research Board. Others will presumably be regarded as matters for the consideration of the Safety in Mines Research Board,

whose new laboratories in Sheffield, as announced in the *Journal* of September 8th (p 472), are to be opened in October, while others, again, must be left to the individual units of the industry itself for solution.

THE INTRATHORACIC AND INTRAPERICARDIAL PRESSURES IN MAN

It has been generally believed, perhaps upon insufficient evidence, that the act of inspiration is an important factor in the mechanics of the circulation. The increase in thoracic volume which occurs when a breath is taken has been thought to draw, not only air into the lungs, but also blood into the heart. That this conception is open to criticism, and that our knowledge of the variations in intrathoracic tension is far from complete, has been shown by Dr Alfred Kendrew¹ in his review of the subject. Over a century ago the work of Carson established the fact that the intrapleural pressure was rather below that of the atmosphere, this finding was later corroborated by Donders, and it has since been commonly accepted that the pressure within the pleural cavity varies between -6 mm Hg in expiration and -7 or -9 mm Hg in inspiration, taking the atmospheric pressure as zero. The fallacy which is tacitly implied in most textbooks of physiology, and which the author seeks to expose, is that this negative pressure results in constant suction of blood from the great veins into the heart. He further argues, supporting the theory of Kroetz, that because the fibrous pericardium is inextensible the intrapericardial pressure must be that of the atmosphere, and that therefore the furtherance of the circulation by negative circumcardial pressure is impossible. There are, however, other aspects than these to be considered. It is clear that if any phase of the respiratory cycle promotes the venous return to the heart it must be that of inspiration, during the expansion of the thorax the additional available space must be filled by air or blood, or both. Air flows steadily into the lungs, and since the pressure in the great veins is generally rather greater than that of the atmosphere, it must be inferred that some of the blood in them helps to fill the expanding thorax. Again, during inspiration, the negative intrapleural pressure must be transmitted directly to the walls of the great veins, which are not inelastic, so that this process may also facilitate venous return. These are probably only subsidiary factors in the mechanics of the circulation, and the author certainly justifies his main contention as regards the part played by pressure changes within the pleural cavities. He regards the fall in venous pressure which occurs during inspiration as due to the increasing capacity of the lungs for blood, the right side of the heart being thereby relieved. It has been argued in the past that were it not for the intrapleural negative pressure blood could not return to the heart and the circulation would stop. That this reasoning is questionable is clear from a consideration of the volume changes in the heart. At any given phase in respiration the contraction of the heart makes more space available in the thorax. That part of this space is filled by suction of air into the lungs has been experimentally demonstrated, but it seems reasonable to suppose that blood flow into the great veins is also promoted. Dr Kendrew has raised very vital problems in his work on this subject, and has obviously given much thought, not only to the physiological and medical issues involved, but also to the underlying physical principles. It will be a pity if his very suggestive paper fails to stimulate further research into the mechanics of the circulation, with special reference to the relation between intrathoracic pressure changes and the venous return to the heart.

FREE IMPORTATION OF SCIENTIFIC FILMS

The Commissioners of Customs and Excise have issued a notice to various scientific societies regarding the importation free of Customs duty of approved scientific films, and explaining the procedure to be adopted by organizations desirous of availing themselves of the concession granted in this connection by the Finance Act, 1928. An account of the incidents which preceded the movement to secure this indulgence was given in the *Journal* of July 14th (p. 63), where it was shown that the effect of the duty hitherto imposed had been to exclude, or to render difficult the importation of, films of considerable scientific importance, but of no commercial value to their owners or others. The question was raised in the House of Commons by Captain Ian Fraser, who was supported by medical members of Parliament, and the Chancellor of the Exchequer—after another representative of the Treasury had stated that the administrative difficulties were regarded as insuperable—ultimately agreed to reconsider the matter. It was suggested to him that the Customs authorities should agree to accept certification by responsible scientific bodies as evidence that certain films merited exemption from duty. The result of Mr. Churchill's deliberations has been the insertion in the Finance Act, 1928, of a proviso that "The Customs duties imposed by Subsection (1) of Section 3 of the Finance Act, 1925, on negative and positive cinematograph films shall cease to be payable in the case of a film which is certified by the Royal Society of London for Promoting Natural Knowledge to be solely an illustration of scientific investigation for exhibition before members of a recognized scientific body, and which is imported only for the purpose of such exhibition free of charge." In the Customs notice referred to above it is stated that any society or person desiring to import films under this concession should, in the first instance, apply to the Commissioners, giving the following particulars: Whether positive or negative, whether developed or undeveloped; length of film in feet; full particulars of the subject of the film; name and address of applicant; proposed method of importation (in passenger's baggage, by parcel post, or otherwise); date of proposed importation and port of entry; if known, name and address of scientific body before which the film is to be exhibited; and the date of exhibition.

INTELLECTUAL CO OPERATION

The movement towards what is known as intellectual co-operation fostered by the League of Nations (writes our correspondent from Geneva), is steadily gaining ground. The Institute of Intellectual Co-operation, domiciled in Paris but a League offspring, is now subsidized by eleven nations. The committee which takes this sphere of the League's work under its control is presided over by Professor Gilbert Murray, in succession to the late Professor Loewy, and has among its members some eminent European scientists, including more than one professor of medicine. Professor Gilbert Murray reported to the present assembly that interchanges of professors and students between universities in different countries had been encouraged, and that there was now proceeding an interchange of secondary school teachers. These interchanges are of the same character as those of public health officers, undertaken by the Health Organization, and appear to be equally fruitful. It is noteworthy that the American Council of Education has placed a sum of money at the disposal of the committee for the purpose of an inquiry into university relations in Europe and the facilities available there for American students. The question of travelling or exchange scholarships has been remitted to a committee of experts with a view—the reference is rather vague—to reaching conclusions that will be applicable not

only to scientific laboratories, but also to research institutes, in the field of humanities and social science." A draft convention has also been formulated with the object of assuring for scientists the financial benefits which are justified by the profitable use of their discoveries—in other words, to prevent the unauthorized and unacknowledged use in one country of the work of a scientist of another. The British Government, however, has found some technical fault in the convention, which as drawn up, it considers, would interfere with industrial activity, and the matter has not at present gone further than the sphere of proposal. An attempt is being made to bring libraries and universities of all countries into a scheme of co-operation whereby scientific or bibliographical information may be made mutually available. Another enterprise aims at the removal of undue hindrances, in the shape of Customs barriers and postal tariffs, to the international distribution of books. It is intended to urge that scientific works, particularly works intended for libraries and scientific institutions, should be exempt from Customs duties. The question of scientific works published in the less known languages has also received attention; it appears that in the countries where such works have been published there is already a sufficient recognition of the need of securing translations in one or other of the more widely diffused languages. The language difficulty, as anyone who has attended an international congress will agree, is the principal hindrance to full international co-operation and understanding. In spite of the skilled army of interpreters at Geneva, difference of language is a constant impediment, leading every day to embarrassment and frustration, and sometimes to even more disagreeable results. If the Committee on Intellectual Co-operation would urge a wider acquaintance with the French language amongst English speaking peoples, and with the English language among the Latin peoples, a great deal of good might be done.

INTERNATIONAL HOSPITAL CONGRESS

The first International Hospital Congress will be held in Atlantic City on June 13th, 14th, and 15th, 1929. Hospital administrators, physicians, surgeons, nurses, architects, engineers, and others interested in hospital questions are invited by the American Hospital Association, which has taken the initiative in this matter. Official invitations to the various Governments are to be sent through the intermediary of the Secretary of State in Washington, and at the same time a questionnaire on the hospital situation and hospital statistics in each country is to be circulated. The official delegates are invited by the American Hospital Association to visit the hospitals of New York, Philadelphia, and Baltimore between June 5th and 12th. Further information may be obtained from the chairman of the International Executive Committee, Dr. Reno Sand, the League of Red Cross Societies, 2, Avenue Velasquez, Paris, or Dr. E. H. Lewinski-Corwin, Secretary-General of the International Executive Committee, Hospital Information and Service Bureau, United Hospital Fund, 2, East 103rd Street, New York.

As announced in our advertisement columns, the Royal College of Physicians of London invites applications for the post of Milroy Lecturer for 1930. The course consists of three lectures, which are to be delivered on Tuesdays and Thursdays in February or March, 1930. A copy of Dr. Milroy's suggestions on the subject of his bequest, and information as to the emolument, may be obtained from the Registrar, Dr. Raymond Crawford, to whom applications must be forwarded by September 29th next, addressed to him at the College, Pall Mall East, S.W. 1.

WOMEN IN THE SERVICE OF HOSPITALS

MEMORANDUM BY JOINT COMMITTEE OF WOMEN'S
ORGANIZATIONS

In the *British Medical Journal* of May 12th, 1923 (p. 821), we reported a conference held in London under the auspices of the National Union of Societies for Equal Citizenship to consider the question of women in the service of hospitals, when a resolution was adopted protesting against the recent decision to exclude women medical students from a number of London general hospitals with training schools. As a result of that meeting a joint committee of women's organizations to promote equal opportunities for women with men in the medical and hospital services was set up, with offices at 15, Dean's Yard, Westminster, S.W. 1, and a memorandum on the subject generally has now been published in pamphlet form (price 2½d post free).

The memorandum is divided into three parts: the first on the training of women medical students, the second on equal opportunities in hospital appointments, and the third on women on hospital boards of management.

Training of Women Medical Students in London

This part of the memorandum opens with a survey of the present position as regards the training of women medical students in the metropolis. One medical school—the London (Royal Free Hospital) School of Medicine for Women—is reserved exclusively for women. University College Hospital Medical School permits not more than twelve women entrants a year, of whom eight are taken from the students of University College leaving four vacancies for students from elsewhere. The medical schools of three hospitals (St. George's, the London, and St. Mary's) which for some years admitted women students, have now closed their doors to them, and three others (Westminster Charing Cross, and King's College) have decided to admit no new women entrants while allowing those at present in training to complete their course. The numbers of women in all stages of the curriculum who availed themselves of these facilities in 1926-27 were as follows: London (Royal Free Hospital) School of Medicine 298, University College Hospital, 59, University College, 44, King's College Hospital, 67, King's College, 54, St. Mary's, 57, Charing Cross 45, Westminster Hospital, 30, making 654 in all.

While paying tribute to the admirable work done by the London School of Medicine for Women, the committee understands that the clinical facilities available for students of that school are already more fully utilized than those of most of the hospitals which have lately closed their doors to women. It feels, therefore, that the facilities to which women are now once more restricted can be regarded as adequate only on the assumption that the number of women requiring training is, and is likely to remain for a considerable period, less than the present figure.

Coming to the suggestion that the influx of women into medicine during the war years was abnormal, and that the number has diminished and is likely to diminish further, and that no hardship will therefore ensue from this drastic reduction of facilities, the committee submits that on the contrary, though the number of medical women may fluctuate from time to time, the general tendency will be towards a steady increase. The following causes are assigned for this anticipated increase: (a) the growing demand for women doctors under local authorities, (b) the strong probability that within a few years either the system of national health insurance will be extended to cover dependent wives and children, or a national health service covering these classes will be set up, (c) the steadily growing demand for women doctors not only among the above mentioned classes, but also among those employing private practitioners, (d) the growth of population, (e) the increased demand that may be expected for doctors to practise in the East, especially in India, (f) the growing need felt by the middle classes, especially the professional classes, to seek careers for their daughters.

Assuming, then, that the facilities now in prospect are inadequate, the committee submits that it is the duty of all those who share the responsibility for medical education in London to remedy this defect. The statutory obligation on the University of London to afford equal educational opportunities to all students without distinction of sex could, in theory, be fulfilled either by permitting coeducation in some of the schools now reserved for men, or by creating fresh facilities for women only.

While expressing no opinion as to the relative advantages of coeducation or separate education, upon which teaching experts, both men and women, are said to be divided, the committee is in favour of free choice, both types of schools being made available. The alleged dislike of coeducation among men students and the arguments based on this should not, in its opinion, be allowed to weigh against considerations of justice and expediency, which call for a fairer sharing, as between men and women, of the training facilities offered by the medical schools, whether this takes the form of joint or of separate education.

To the claim that because most of the existing institutions have hitherto been 'men's medical schools' women have no rights in regard to them, the following reply is made:

(a) The existing male monopoly in the hospitals and medical schools is a survival of conditions under which women were excluded altogether from the medical profession and from nearly all public offices. It cannot be held to have created a vested interest. These institutions exist for the benefit of neither men nor women doctors but of the sick and suffering.

(b) The hospitals and medical schools are supported by the public irrespective of sex. So long as these institutions were maintained mainly by individuals who could choose the destination of their subscriptions there may have been some justification for the claim of their committees and boards to administer their affairs just as seemed good to them, so long as their subscribers were satisfied. But the individual subscriber to an individual hospital is becoming an increasingly less important factor in hospital finance in comparison with funds to which men and women subscribe more or less compulsorily—e.g. through taxation or deductions from wages or contributions to street or church collections, etc.

Equal Opportunities in Hospital Appointments

It is, the committee says, plainly a great handicap to women in their medical careers if the appointments normally open to recently qualified students, such as those of house physician and house surgeon, are available for them in a much smaller proportion than to male students. We would go further and remark that equality of opportunity is also necessary with regard to the more important honorary appointments.

We urge, therefore, that whatever changes are made to provide further training facilities for women shall be made in a large-minded and ungrudging spirit. In claiming for women full equality of opportunity in this and every other part of the medical service, we wish to make it plain that we do so not merely as a matter of justice to women doctors themselves, but equally or perhaps even more in the interests of the public whom they exist to serve. Where issues of health or sickness, of life or death are at stake, nothing but the best is good enough. We believe it is generally admitted by the medical profession that women doctors on the whole have loyally upheld its standards, have never sought to use their sometimes exceptional economic position—their lesser burden of dependency—to undercut or outbid their male colleagues. We wish it were equally plain that the same spirit of loyalty and fair play was holding in check the not unnatural desire of some of the junior or less well qualified male members of the profession to limit the number and opportunities of their women competitors.

Women on Hospital Boards

Under this heading the committee expresses astonishment at that even in the sphere of lay management a considerable number of hospitals either exclude women altogether or have placed them only on subordinate committees entrusted with minor functions, seeing that the duties of boards of management are concerned very largely with questions of nursing and domestic administration. The memorandum concludes with a table showing the position with regard to women on committees of management in those London hospitals which have recently excluded women students from their medical schools.

Canada.

[FROM OUR CORRESPONDENT IN MONTREAL]

Mental Hygiene in Canada

It can hardly be said that problems of mental hygiene occupy a larger place in western Canada than elsewhere in the country, but they do exist there, as elsewhere, and keen interest is being shown in their study. This was found to be the case by the director and secretary of the Canadian National Committee for Mental Hygiene on a visit to the four western universities in June last. Each of these centres was found to have trained workers who were willing to co-operate with the committee in every respect, and to follow out suggested studies. The immigrant population provides many problems of this nature, and it is being recognized that the large proportion of the population of the mental hospitals, gaols, and charitable institutions which is being contributed by the incoming settlers may be reduced by sympathetic and intelligent study of the people on their arrival, of their capacity for education, their industrial and artistic capacities, their adaptability, and so on. Thus, naturally, is a large programme, it requires the co-operation of a mental hygienist with the anthropologist, the educationist, and the sociologist. But these formidable-sounding specialisms only serve to stimulate the irrepressible optimism of the West, and the various problems are being faced with cheerful confidence. It is no small additional stimulus to recall that Canada is spending more than nine million dollars a year for the care of end-cases of mental and social disharmony.

Medical Aspects of Immigration

It is to be hoped that immigrants will gradually come less and less to provide material for the care of the mental hygienist. A timely paper on the medical aspects of immigration into Canada has been published by Dr J D Page, chief of the Immigration Medical Division of the Federal Department of Health. In this he reviews the whole history of the medical side of the Canadian Immigration Law since its inception in 1903 and shows that while the law was well designed to protect the country from the entry of medically unsuitable settlers, its operation as regards the medical examination of the immigrants was always hampered by an insufficient number of examiners. As time went on steps were taken to remedy this lack, but it gradually became evident that the weakness of the system lay not so much in the number of men detailed to examine immigrants as it did in the fact that the examinations were made on the wrong side of the Atlantic. It was the realization of this that finally led to the appointment of medical men by the Canadian Government, by whom all intending immigrants were required to be examined before embarkation. This system has only been in operation since February last, and it is therefore too early to say how it will do, but the underlying principle is sound, and it is expected that it is only a matter of the medical examiners gaining sufficient experience to make the plan as successful as can be expected. The criticism which it produced was traced to certain shipping interests, these professed to see in the new regulations a deterrent to immigration, and in support of this it was demonstrated that the immigration to Canada for the first three months of this year was 12 per cent less than during the corresponding period in 1927. It would be almost sufficient to reply by saying that if, as was possibly the case, this falling off was partly due to stricter medical examinations then the country could hardly be regarded as having suffered much loss. There is also the fact to be considered, however, that a corresponding decline in immigration (indeed, a greater decline) was noted for the same period to Australia, New Zealand, and the United States.

Annual Meeting of the Canadian Medical Association

The annual meeting of the Canadian Medical Association has an increased attendance each year, with a continual development of interest in general medical affairs. This is all the more noteworthy because it is only within the last seven or eight years that it has been possible to feel that the organization of the Association has really taken root.

We can now see it bringing forth its fruit in increasing abundance. The meeting this year, however, was a little different from those of recent years. It was held at Charlottetown, Prince Edward Island, a new venue, and one which it was felt at first might cause difficulty in the matter of accommodation, in respect of which the modern convention is apt to be so exacting. In addition to this Prince Edward Island is at the extreme eastern extremity of the Dominion, and this would certainly diminish the number of those coming from the West. The completeness with which the first difficulty was surmounted might have been hoped for, but could not have been quite expected. The people of the island as a whole seemed to take the visitors in hand in the fully successful attempt to live up to their traditional hospitality. The second difficulty was largely overcome by an exceedingly pleasant scheme—the chartering of a steamer to bring down members from the central and western regions. Many took the opportunity of a trip which was planned to include the historic and picturesque, and the party arrived at Charlottetown in the best possible humour for the convention. It may be that the programme of the convention brought out no very striking medical developments, as the papers were chosen chiefly with regard to the ordinary problems of everyday general practice. Thus, however, in the opinion of many was a distinct advantage. To one member at least—and he probably expressed the feeling of several—the meeting this year was in the nature of a pause by the C.M.A. to gather strength for the problems which it will face in greater degree as the country develops. And no more beautiful part of Canada could have been chosen for reviewing the past and making plans for the future. What happier augury, too, for the future of the Association could there be than its gathering at this stage of its growth in a city so full of historic memories in the binding together of the Dominion of Canada?

England and Wales.

Vital Statistics for 1927

The Registrar-General's *Statistical Review of England and Wales for 1927*, Tables, Part II Civil, can now be obtained at H.M. Stationery Office (price 5s.). The volume contains statistics of population, marriages and divorces, births, passenger movement, parliamentary and local government elections, and vital statistics of the British Dominions. The estimated population in thousands of Great Britain and Ireland was

	1926	1927	Increase + or Decrease— per cent
England and Wales ..	37,067	39,290	+0.6
Scotland ..	4,897	4,892	-0.1
Northern Ireland ..	1,254	1,253	-0.1
Irish Free State ..	2,970	2,938	-0.4
Total ..	48,188	48,393	+0.4

The number of marriages solemnized in England and Wales during the year was 303,370, and was equal to a rate of 15.7 persons married per 1,000 persons living. During the three years 1919-21—following demobilization after the war—the rate averaged 19.0, which was the highest recorded since the establishment of civil registration. The rate in succeeding years showed an almost continuous decline until 1926, when it was 14.3, the lowest since 1886. The number of deaths made absolute during the year was 3,190, or 568 in excess of that for the previous year. Excluding the exceptionally high number—3,080—in 1921, the total for 1927 is the highest on record. The births registered during the year numbered 654,172, and were equal to a rate of 16.6 per 1,000 population. This is the lowest recorded rate, and is no less than 1.1 per 1,000 below the abnormally low rate recorded during 1918. Not only has the birth rate declined, but the actual number of births is the lowest

registered since 1855, when the population of England and Wales was only 18,829,000, or about 48 per cent. of the estimate for 1927. The number of illegitimate births was 29,023, or 44 per 1,000 total births, and was 568 below that in 1925. The proportion of male to 1,000 female births was 1,042. This proportion showed a great increase during the war years and attained a maximum of 1,060 in 1919, since when the decline has been almost continuous, and the proportion is now approximating that which prevailed in the period immediately preceding the war. The number of parliamentary electors on the autumn register was 19,585,872, of whom 11,094,031 were males and 8,491,841 females.

International Society of Hydrology Visit to English Spas

The first visit of an international medical party to the British spas will take place next month, on the occasion of the annual meeting of the International Society of Medical Hydrology, which begins on Tuesday, October 9th. On the evening of that day the members will be received at a *conversazione* at the Royal Society of Medicine by the president-elect, Lord Dawson of Penn, who will preside over the discussions to be held in London on the two following days. The medical subjects for discussion include the relation between the State, the health resort, and national health insurance, and the humoral factor in disease. On Friday, October 12th the members will leave London for Harrogate, proceeding subsequently to Buxton, Dronwigh, and Bath, and returning to London on Wednesday, October 17th. During the tour there will be numerous discussions and demonstrations, visits will be made to places of interest, and the members will be entertained at various social functions. It is expected that the party will number over a hundred, representing seventeen nations. A limited number of places are available for medical practitioners interested in the objects of the meeting. Particulars may be obtained from the honorary secretary of the society, 139, Marylebone Road, London, N W 1.

Post-graduate Work in Manchester

Manchester offers facilities for post-graduates of a scope that is perhaps not always realized by local practitioners. For the year 1928-29 various courses have been organized—some by the University and some by the local hospitals. Those at the University are courses on stated subjects, while those at the hospitals are generally made up of independent lectures given by members of the staff. The University is providing a short intensive course in gynaecology and part-time courses in diseases of the eye and skin, in x-ray work, and in clinical pathology. The Royal Infirmary provides lectures throughout the academic year on Tuesday and Friday afternoons, that on October 23rd—the Lloyd Roberts lecture for the year—will be given by Sir Berkeley Moynihan, on "Some problems in gastric surgery." The post-graduate lecture on pneumothorax which Dr A. Ramshotbottom had arranged to deliver on September 25th has had to be cancelled owing to illness, a demonstration of surgical cases by Mr W. R. Douglas will be substituted. The staff of Ancoats Hospital will give short courses on the sympathetic nervous system, on minor operations on the ear, nose, and throat, and on advances in antiseptics.

Resignation of Dr Noy Scott.

Dr S. Noy Scott, who has retired from the post of medical officer of health to the Plympton St Mary Rural District Council, has completed thirty-five years' service in that capacity. At a recent meeting of the council, when his resignation was announced, a resolution was adopted expressing the council's regret at his decision and asking if it was not possible for him to reconsider the matter. Dr Noy Scott, however, explained that his retirement had been forced upon him largely by health considerations. A warm tribute to his work in the Plympton district is given in a leading article in the *Plympton and South Devon Times* of September 6th, which states that "he has regarded his post in exactly the spirit which Sir George Newman has endeavoured to breathe into the whole health service of the country," and describes how he has kept abreast of every forward movement in public health, so that during his term of office "the local machinery has been made

to work up to its fullest capacity." The article concludes "A skilled, diligent, and fearless medical officer like Dr Noy Scott cannot have kept watch and ward upon the public health of a district for five-and-thirty years without having made an enormous contribution to public welfare and individual happiness. He retires with the knowledge that a sound tradition has been established, and that the great sanitary policy at which he has aimed, based on a copious and constant water supply, is now certain of realization within a very few years. His neighbours thank him sincerely for his public labours and his private friendliness and wish for him many happy years of comparative leisure in which to watch the results of his long exertions come to fruition."

Gaseous Content of Buxton Water

At a meeting of the Buxton Medical Research Society on September 7th at the Devonshire Hospital, Mr J. Race, the biochemist to the hospital, communicated to the Society the result of the recent analysis of the gases issuing from St. Anne's Well made by Dr Judd Lewis. This showed the rare gases to be 120 per cent. of the total volume and to contain 96.6 per cent. of argon, 3.4 per cent. of helium, and no neon or other such gas. The absence of neon was considered an interesting feature of the analysis, since it appeared to exclude atmospheric air as a source of the helium, and afforded a sharp contrast with the gas at Bath, which, like atmospheric air, contained considerably more neon than helium. Mr Race discussed the possibility of the helium being due to the disintegration of radium, and expressed the opinion that the more probable source was a mineral such as cleveite, which had been shown to yield helium on heating. As cleveite contained the oxides of uranium and lead, the first and last members of the uranium (radium) series, this source could not be dissociated from the general idea of radio-activity, but the nature of the relationship could only be conjectured. The output of radium emanation in the gas had been estimated at 3,000 millimicrocuries per hour, a figure which compared very favourably with that of most of the Continental spas. Photographs were exhibited showing the relative effect of various waters on the growth of mustard seeds. Seeds soaked in the radio-active Buxton water germinated quicker and grew more rapidly than in tap water or in a natural water practically identical in composition with the Buxton water but free from radium.

Ireland.

Change in the Health Insurance Medical Certification Area

THE Irish National Health Commission (Irish Free State), decided some time ago to change the area of the pool for the payment of medical certification of sickness benefits under the Insurance Acts from the dispensary district to the county. The Irish Medical Committee, on behalf of the medical certifiers, forwarded a unanimous protest to the Commission against the change, but the Commission did not accede to its request, and has now addressed a circular letter to each medical certifier. The reasons given by the Commission for the change are not considered to have much foundation. In the absence of a panel system for medical certification the dispensary area was held to be the fairest alternative, as it corresponded approximately to the actual and potential practice of the medical certifiers, who did the maximal portion of the work. The Irish Medical Committee is asking the local medical committees to consider the question. In the circular letter addressed to medical certifiers the Commission states that it has had under review for a considerable time past the method of distribution of the moneys available for this service among the doctors undertaking medical certification. While the distribution of the funds available amongst the certifier in the county boroughs and urban districts has worked out generally with equitable results to the doctors, very serious anomalies have arisen in certain other certification areas included in the counties. In these areas the ultimate basis of distribution of the money available for certification under the present scheme is the dispensary district, the amount

allocated to each county being subdivided to ascertain the portion available for each dispensary district, the basis of subdivision being the number of insured persons resident in each such district. The Commission states that it has decided to discontinue the use of the dispensary district as a basis for calculating the payments for medical certification for the following reasons:

1. The adoption of the dispensary district as the unit of distribution has resulted in certifiers in adjoining dispensary districts receiving widely divergent rates of remuneration per certificate issued.

2. The system is unsatisfactory owing to the fact that it is not possible to obtain accurate figures of the number of insured persons in the dispensary districts without incurring expense, which would be very much higher than the results obtained would justify.

3. The making of calculations on the dispensary district basis entails a large amount of work and expense in this department, and it is not possible to defend the continuance of expenditure on a system which produces such obviously inequitable results.

The Commission feels that, in the circumstances, it would not be justified in continuing the provision in the schedule to the agreement necessitating the apportionment of the moneys to dispensary districts, and it has decided that, as from January 1st next, the money available for each county area will be divided amongst all the certifiers operating in that area without any reference to dispensary districts. No alteration will be made in the present method of distribution in county boroughs and urban districts. It should be understood that the proposed change relates only to the method of distribution, and does not in any way affect the total amount payable for medical certification. Practitioners are asked, if they are willing to continue the medical certification of insured and exempted persons after the date of the alteration in the method of distribution of the moneys available under the scheme, to sign and date the enclosed forms and to return them to the department.

Correspondence.

TONSILLECTOMY AND REMOVAL OF ADENOIDS

Sir,—Sir Charters Symonds's advocacy of ether anaesthesia for safety and efficiency is one of the most instructive points brought out in the correspondence on this subject, but I would support Dr Wright Lambert's practice of open ether administration, dispensing with any Clover inhaler. This is the method we have employed in Bristol since 1887, when Dr A. L. Flemming first introduced the two drop-bottle method of open anaesthesia. True, at first the one bottle of chloroform was used to supplement the ether dropped on the mask from the twin bottle, but ere long the former was dispensed with and ether alone administered by Dr Flemming for most of the abdominal, intracranial, and other operations. Flemming's methods and experiences were published in the *British Medical Journal* for September 17th, 1910 (p. 767), and were referred to by Hewitt in the fourth edition of his classical work on anaesthesia.

For many years I have never seen a Clover or other inhaler used, and am convinced that there is no increased liability to haemorrhage from ether, and that recovery from light ether anaesthesia is as quick and comfortable as after chloroform. That ether is far safer than chloroform seems borne out by statistics as well as personal experience, and in operations on the nose and nasopharynx an anaesthetic that stimulates the vagus centre in the medulla is the more desirable, since stimulation of the olfactory nerve induces reflex cardiac inhibition.

Mr Lowndes Yates raises the extremely important subject of nasal sepsis as not seldom present and being the determining cause of adenoids and septic tonsils. I have myself frequently urged the necessity of examining for the existence of nasal sepsis, and at any rate the desirability of exploring the maxillary antra, since such a procedure need not occupy more than one minute at the end of the operation on the tonsils and adenoids. When a nasal sinus infection exists it seems to cause recurrence of adenoids, which lymphoid hypertrophy is in a measure protective. But to leave a child to grow up with an unrelieved nasal sinus infection is surely a grave misfortune.—I am, etc.,

Clifton Bristol Sept 18th.

PATRICK WATSON-WILLIAMS

THE FALLING BIRTH RATE

Sir,—In your article on the falling birth rate (September 15th, p. 499) you conveniently summarize some prepositions made in a brilliant paper by Dr F. A. E. Crew (p. 477), and I should like to comment upon them.

1. "There is a law of population growth which occurs in cycles, following in the main a curve of a definite type." This idea is, in a new garb, the old Malthusian one that whenever man made an advance in food production his death rate fell and his numbers consequently leapt up, for a time.

2. "The birth rate is falling now because we are at the end of such a cycle." This suggests that the birth rate fell at the end of previous cycles, which there is no reason to believe.

3. "Density is one of the controlling factors." If great density reduces fecundity, it is surprising that there has been no decline of the very high birth rate of India and China, and that everywhere the fertility of the slums is always the highest.

4. "Voluntary control of conception has undoubtedly prevented the birth of many individual babies, but it may be doubted whether this has appreciably affected the crude birth rate or population growth cycle." These last eight words suggest that crude birth rate and population growth are synonymous terms! And surely it cannot be doubted that the tremendous fall in the crude birth rate of England and many other countries between the years 1876 and 1914 was mainly due to contraception, the great propagandist for which started in 1876. Every big inquiry into the subject has reached that conclusion. But contraception, although it has immensely affected the crude birth rates, has, I agree, not appreciably affected the population growth cycles, because it has not affected the rates of natural increase of population—that is, the fall in the birth rate was in most countries accompanied by a very similar fall in the death rate, as neo-Malthusians have long been pointing out. One effect of confusing the birth rate with the population growth, and of suggesting that contraception does not reduce birth rates, will be to hinder the much-needed movement for encouraging the poor to have no more children than they themselves can provide for.—I am, etc.,

London S.W., Sept 15th.

BINNY DUNLOP, M.B., Ch.B.

SEA SICKNESS

Sir,—Reading the letters of the different observers who kindly noticed my paper on sea-sickness (*British Medical Journal*, May 5th, 1928, p. 752), I have been struck, not only by the facts that we are ignorant of the cause of sea-sickness, and that we have no remedy for the disease, but by the suggestion that diagnosis here has its difficulties too, and that we must discriminate between true sea-sickness due to labyrinthine irritation and sickness at sea for which some digestive trouble is to blame. This is a subtle distinction that cuts the ground from under those who have been accustomed to think that sea-sickness may be caused by any sense impressions that may affect the vomiting centre at sea. Among these impressions disturbances of the endolymph may play a part, and no doubt they are the cause of the vertigo which is an accompaniment of many cases, but few will deny that sea-sickness may happen without vertigo, and there are many who are not satisfied with the existing evidence that a purely mechanical disturbance of the labyrinth is at the bottom of those cases where it does.

It is common ground that the vestibular mechanism is vulnerable from many directions: it may be affected by gross changes, permanent or temporary, in the labyrinth itself by any discord between impressions arising in the cerebellum, or in the eye muscles, or in any sense organ, with a consequent failure to co-ordinate them, by many toxins. Poisoning by nicotine occurs to the mind, and by this is meant, not the chronic toxicæmia that results in a neuritis of the eighth nerve, but the temporary indisposition that may follow the smoking of a strong tobacco. The resemblance between the symptoms of over-smoking and of sea-sickness is very close, and in the former case it would be regarded as unreasonable to suggest that the toxin

chase the labyrinth as its first mark, whence its effects spread to the vomiting centre and the pneumogastric.

Lastly, there is the psychical avenue for attack, and while the giddiness that affects many people when climbing or looking down from a height is excluded by Baniy from the true vertigo, it is dangerous to speak of functional disturbances, and to say that a man is giddy with apprehension, or that one's head is in a whirl from bewilderment or what not, is no more figure of speech, but describes a physical condition for which there is no external senso impression to account.

For a long time, though convinced that the vertigo now in question is caused by unwonted movements of the endolymph, and believing that true seasickness could occur without it, I looked for a general cause that might affect the labyrinth and the vomiting centre, either independently or together, and I give below the results of my search for what they are worth.

The patients upon whom the experiment was made number 25—too few to dogmatize upon but numerous enough to make it possible to draw reasonable conclusions from the evidence obtained from them. All were emigrants from central Europe and Syria, adult men and women of good physique—mostly simple people, intelligent enough to understand the questions put to them, and without the imagination that makes the more cultured especially among the Latin races so liable to seasickness. Most of them had travelled for many hours in trains, and the Syrians had been a fortnight or more on the journey to La Pallice. True sickness had occurred in 8/6 of these persons being Jews. In the 6 there had been headache and vomiting and in all but one vertigo as well. The exception was a Rumanian Jew, in whose urine there was a trace of sugar but no diacetic acid. The urine of the remaining 7 contained diacetic acid, some more, some less.

Of the 17 who were not train sick 11 suffered from vertigo in addition to their other symptoms, and in 2 of these the dizziness was not felt until some hours after the attack of sea sickness began. Both patients had kept about fighting the nausea and only after lying down for some time did they complain of vertigo. One was so bad that, though he could not stay in bed but lay on the floor clinging to a ringbolt and thus when the motion of the ship was not excessive. This man was a Syrian Jew, highly intelligent and anxious between the paroxysms to discuss his symptoms. He had been to sea before and had suffered from sickness but never from vertigo.

In 9 patients vertigo was the first complaint, and it was interesting to note that in 4 of them the subsequent nausea was slight, the vomiting being more of a painless regurgitation than a cataclysm such as shook the rest. The urine of 4 of these patients contained diacetic acid.

There remain the 6 in whom no vertigo occurred at any period of the attack. There seemed to be no justification for putting them in a division by themselves (they showed all the classical symptoms—cold sweat, pallor, yawning, weak pulse and vomiting). Two were badly affected and lay like dead folk while the others were ordinary cases and could take a little interest in their condition. In all 6 the urine contained diacetic acid from the first and the blood sugar in one of the bad cases was 0.07.

Impossible as it is to generalize from so small a number of cases, from the presence of diacetic acid in so large a proportion from the very beginning of the attack, it seems fair that an acidosis should be allowed to share at least with the labyrinth in any theory of the causation of seasickness. Neither the paths from the labyrinth nor the nature of the impulses they transmit are known with accuracy, and any suggestion with regard to either must be speculative. A theory that sea sickness may be due in the first instance to an acidosis that affects the labyrinth, the vomiting centre, and the sympathetic (in the order named, or inversely), or affects one or more to the exclusion of the others—such a theory is speculative too, but it has a claim to be considered with respect. So with the suggestions of the mechanical effect of the rise and fall of the ship on the hepatic circulation by way of the varying pressure of the abdominal contents, the appearance of irregular waves in the cerebro-spinal fluid, the pious thought that sea-sickness is the effort of a beneficent Providence to fit man for an unusual environment. Who can deny the possibilities of all these?

These reflections are not without interest in regard to treatment. The public expects too much, travellers demand a drug that will prevent seasickness, or cure it when it attacks them, but few will take ordinary precautions before a voyage, and fewer still will trouble to

make that effort which can control even the raging of the endolymph, and enable them to face the sea with courage and common sense. Faith is the great thing needed, and in its light the bronchus, the belly-band, and the amulet will fulfil their destiny, occupation is a help, and many find salvation in a job of work, for others, the tablespoonful of Worcester sauce or the more sophisticated piano oyster. Lastly, the earnest person, who believes that here Providence is at work, and sea-sickness a thing that has to be, may starve himself a while, keep his bowels open, and wait hopefully for the dawn—I am, etc.,

R ALLAN BENNETT, M.D., M.R.C.P.,
Surgeon Pacific Steam Navigation Company

Havana September

SIR,—The letter of Dr A. C. Ingle of September 8th (p. 467) recalls to my mind occasions a quarter of a century ago—I was then a ship surgeon on the North Atlantic route—when the late Dr J. R. Stocker of the Board of Trade used to discuss with me ideas regarding the causes of sea sickness. He had himself had considerable experience at sea, and he maintained that the respiratory disturbance was more important than disturbances connected with the semicircular canals, the cerebellum, or other centres.

Those discussions caused me to form the opinion that, as most people inspired while the ship—or rather, the part of the ship where they were located—was rising, and held their breath till the downward motion was experienced, thereby producing a course of irregular breathing, there probably followed some irritation in the region of the throat, and, as tickling of the fauces by a feather induced nausea and vomiting, it was quite reasonable to expect that another form of irritation would produce a similar effect, the mechanism in both cases being through the glosso-pharyngeal nerve and the vagus.

Following up this idea, I frequently, on voyages from New York, formed schools of what we called “anti sea sick drill,” consisting chiefly of young American men and women who were on their first voyage to Europe, and showed them how to breathe regularly and freely in spite of the movements of the ship, with the result that—I regret I have no statistics—sea-sickness was reduced to a minimum among those who persisted in the practice—I am, etc.

Southampton Sept 12th.

D. D. F. MACINTYRE, M.B.

INTRAVENOUS MEDICATION FOR ACUTE INFECTIONS

SIR,—In the *British Medical Journal* of September 8th (p. 463), Dr A. M. N. Pringle draws attention to the great value of colloidal argentine administered intravenously in the treatment of puerperal septicæmia. He records twenty-seven cases of severe puerperal infection treated consecutively with intravenous injections of colloidal argentine with only one death. I think this a very remarkable and satisfactory result.

My own experience of the treatment of acute blood infections with colloidal argentine has been very encouraging. Several cases of severe streptococcal blood infection have made good recoveries. One case of pneumococcal and staphylococcal blood infection following a severe post-operative peritonitis was completely cured, the blood becoming sterile after repeated intravenous injection of 25 to 20 c.c.m. I consider it a most valuable agent in the treatment of such cases, which appear to be desperate. I have not found it, however, to be invariably successful, some cases of streptococcal blood infection in which the patients' powers of resistance were no doubt abnormally low have succumbed in spite of repeated doses of this agent. It has the great advantage compared with some other drugs used intravenously—for example, mercuriochrome—in being, in the dosage used, apparently quite non-toxic. I think, however, that mercuriochrome has special advantages in *Bacillus coli* infections, and in such cases I would give it the preference—I am, etc.,

HENRY H. BROWN, M.D., F.R.C.S.,
Consulting Surgeon to the East Suffolk Hospital

Ipswich Sept 10th.

HLRPS AND VARICELLA

SIR,—Dr Gray Hill is to be congratulated on his valuable contribution (August 4th, p 197) to this ever popular discussion, in the shape of eight first-cases of chicken-pox traceable to an original herpes zoster, making a percentage of 23.5, and this in spite of careful isolation.

The lower percentage (16) in Dr Cowie's report¹ need not invalidate, as Dr Hill seems to imply, the general argument for a common origin, as, after all, percentages depend to a large extent on environment. One may imagine the case of a teacher who, in spite of an attack of shingles, continues her teaching in a school of 100 young children. One child contracts chicken-pox, which spreads in the usual way until fifty have succumbed to the disease. This works out, of course, at 2 per cent. On the other hand, take the case of shingles in a mother on an isolated Rhodesian farm. She has an only child, an infant at the breast, who contracts the disease in the shape of chicken-pox.² At another farm, equally isolated, a ten-year old girl is taking arsenic for her chorea and at the same time acting as mother's help with the youngest member of the family. The arsenic induces a shingle eruption, and the baby, being in close daily contact with its sister, contracts a mild chicken-pox. The other members of the family, having all had chicken-pox at an earlier period of their existence, escape infection on this occasion.³ Taking these two cases together we get a percentage of 100, which is clearly due to the chance that no opportunity offers itself for the further spread of infection.

Some light can, I think, be thrown on the question of immunity by a study of those less common cases in which the herpetic is followed by the varicellar eruption in the same individual. The term "concurrent" in this connexion, although often used, is apt to mislead one as to the actual sequence of events. No case has been yet recorded in which the two eruptions appear simultaneously. In the *British Medical Journal*, during the period 1913 to 1927 inclusive, 176 cases of the relationship are recorded, 35 of these are instances of the occurrence of both eruptions in one patient, and in every case the shingles eruption is the first to appear, the chicken-pox following after a period of one to four days.

In Head and Campbell's classical article on the pathology of herpes zoster⁴ a case of the double eruption is mentioned with an interval of twenty-four hours only. It is noteworthy that these two careful observers had no hesitation in giving the chicken-pox eruption its true title, aording the now (may we hope?) obsolete term "generalized eruption." These cases show that a distinction, even if slight, must be made between the two eruptions, sufficient at any rate to affect the question of immunity. The rule of sequence is invariably the same in not one of the 35 cases alluded to above do we find the varicellar preceding the herpetic eruption. If we also bear in mind the difference of selective action—zoster having a predilection for the posterior nerve roots and varicella being a systemic infection—I think we have an additional reason why there need be no reciprocal immunity. The common origin, however, confirmed bacteriologically by Kundratitz⁵ can surely no longer be an open question, as some would have us believe—I am, etc.,

Capetown

W P LE FEUVRE, MRCS, LRCP

TOXIC EFFECTS OF ASPIRIN

SIR—Some three or four years ago I read in the *Journal* a letter warning your readers that ulceration of the buccal mucous membrane was frequently caused by aspirin, and my experience since then has entirely confirmed your correspondent's statement. Recently I have had occasion to attribute another pathological condition to the use of the same drug. The following is a brief note of the case.

The patient a man aged 52 has been in the habit of taking aspirin during the past nineteen years for the relief of febrile

attacks, to which he is somewhat prone, as well as for rheumatic myalgia and migraine. The amount of aspirin ingested would be, it is estimated, about ten grains per week on the average.

A very severe attack of cheilopompholyx, of both hands occurred in 1916 incapacitating him from all work for seventeen weeks. Each year elapse then he has suffered from similar attacks of varying severity, always worse in warm weather. Internal treatment and local applications were of little utility—the only remedy which gave relief from the almost intolerable itching being exposure to small doses of x rays. For the last two or three years the dysidrosis has been practically chronic with acute and subacute exacerbations and only few and brief intermissions.

Last year the patient was warned by both a dermatologist and a radiologist that further exposure to x rays might be followed by serious results, and this treatment was not again resorted to. During last winter, and until the spring of this year, the skin of the hands was never entirely normal at the best there was excessive dryness with exfoliation of the epidermis. In the spring, aspirin was suspected as a possible source of aggravation, and its use was therefore entirely discarded. The state of the skin immediately began to improve, and has continued to do so steadily despite the onset of summer. Throughout the recent warm weather there has been no recurrence of any kind, and the skin of the hands is now entirely normal though no treatment other than the relinquishment of aspirin, has been attempted.

I am, etc.,

Wylam Aug 30th.

INDIAN MEDICAL SERVICE
AMENDMENT OF STUDY LEAVE RULES

THE following amendment to Rule 10 of the Study Leave Rules for the Indian Medical Service published with Army Department Notification No 890, dated July 9th, 1926, has been made by the Secretary of State for India in Council.

After the penultimate paragraph of the said rule there shall be added—

Study allowance may be given at the discretion of the Government of India or Local Government for any period up to fourteen days at one time during which the officer is prevented by sickness duly certified by a medical practitioner from pursuing the sanctioned course of study.

The following have been appointed on probation to permanent commissions in the Indian Medical Service: Captain F R W K. Allen, I.A. (ret.), Messrs J S McMillan, V E M Lee, M R Simlar, G B W Fisher, R A Paton, A V O'Brien G F Coudon, S T Davies, E S S Lucas, H W Farrell, D Tennant, H S Smithwick, and F W H Cangehy.

NORTH PERSIAN FORCES MEMORIAL MEDAL.

THE War Office announces that Dr W H Dye, Colonial Medical Services has been awarded the North Persian Forces Memorial Medal for the year 1927 for his paper "The relative importance of man and beast in human trypanosomiasis" published in the *Transactions of the Royal Society of Tropical Medicine and Hygiene*, November, 1927. This medal is awarded annually for the best paper on tropical medicine or hygiene published in any journal during the preceding twelve months by a medical officer, of under twelve years service, of the Royal Navy, Royal Army Medical Corps, Royal Air Force, Indian Medical Service, or of the Colonial Medical Service, provided the Memorial Committee considers that any of the papers published has attained a standard of merit justifying an award.

DEATHS IN THE SERVICES

SURGEON CAPTAIN JOHN CHRISTOPHER DURSTON R.N. (ret.), died at Ramsgate on July 26th. He was educated at St Thomas's Hospital, and after taking the MRCS and LRCP Lond in 1893, entered the navy in the same year. He attained the rank of fleet surgeon, afterwards changed to surgeon commander, on November 14th 1907, and retired on January 1st, 1922, on reaching the age limit with an honorary step as surgeon captain. In his early years of service he acted as surgeon in China, Japan and on the Pacific station, and again served in China as staff surgeon on H.M.S. *Flora*. During the early part of the great war he served as fleet surgeon on H.M.S. *Defence*, flag ship of the cruiser squadron in the Mediterranean then in charge of the Naval Hospital at Hauboulne, and later as surgeon commander on H.M.S. *Barham*, in the second battle squadron. After retirement he became assistant medical officer of the Haine isolation hospital in Thanet, and a few months later became medical officer, resigning on account of ill health in 1926.

Obituary.

JOSEPH JOHN PERKINS, M.B., F.R.C.P.,

Consulting Physician to St Thomas's Hospital the Brompton
Hospital for Consumption, and King Edward VII
Sanatorium Midhurst

WE have to announce with deep regret the sudden death in London, on September 13th, of Dr J J Perkins, whose name was for many years prominently associated with the prevention and treatment of tuberculosis.

Joseph John Perkins was born in 1863, and was educated at Owens College, Manchester, Emmanuel College, Cambridge, and St Thomas's Hospital. He graduated M.B., B.Ch. Camb. in 1891, and in the same year obtained the diplomas M.R.C.S., L.R.C.P. Six years later he became a member of the Royal College of Physicians, and in 1902 was elected Fellow. Dr Perkins took special interest in tuberculosis and pathology from the commencement of his medical career. He had held the posts of pathologist and assistant physician to the City of London Hospital for Diseases of the Chest, at St Thomas's Hospital he was appointed physician and lecturer on medicine, and his quiet but keen interest in the students, together with his genuine friendliness to his colleagues, won for him a very deep and wide affection. As physician to the Brompton Hospital for Consumption he played an active part, both as regards clinical treatment and also in the general progress of this institution, until his retirement from practice. Dr Perkins was a member of the council of the National Association for the Prevention of Tuberculosis and served with enthusiasm for many years as its honorary secretary. He was vice-president of the Section of Medicine at the Annual Meeting of the British Medical Association at Portsmouth in 1923, when he opened the discussion on chronic bronchitis.

We are indebted to Dr H G TUNNEY, consulting physician to St Thomas's Hospital, for the following appreciation.

These meagre notes express, from the point of view of an old friend and colleague, some of the more personal aspects of the life which has just come to so tragic an end.

As a hospital physician and teacher there is no doubt of Perkins's success. He was an attractive lecturer on systematic medicine, and on his ward rounds he was followed by a large class. In his special line of work—that of pulmonary disease—he was a recognized authority. He acquired a considerable private practice, and showed himself most helpful and trustworthy as a consultant. His physical examination was thorough, the opinion he formed definite, and his recommendations for treatment practical, so that he gained the confidence of both patient and practitioner. But he wrote little, and very rarely took part in or even attended the meetings of the various professional societies. The majority of his hospital colleagues, though they were always on the best of terms with him, rarely saw him unless their hospital days happened to coincide with his. All this sounds very much as if he were something of a recluse, and yet nothing could be farther from the truth. Perkins was, in fact, a man with a very definite faculty for friendship. In addition to a large circle of acquaintances he had a smaller number of intimate friends. These remained the same year after year, and even decade after decade. He never married, and of course his circle did not escape the two rocks which await the established bachelor's friendships—marriage and death—but the first was avoided by the satisfactory method of the wife becoming an additional friend, the latter, however, took toll of late years, and the gaps so made were never filled. But outside these circles of friends and acquaintances, and outnumbering them manifold, there are those who feel themselves bound to him by the strongest ties of gratitude and affection. Probably their existence was hardly suspected by him—for he was the most modest of men—but their numbers have been steadily growing throughout his professional life. They include many members of the medical profession, patients (both hospital

and private), and every grade of nurse. If only it were possible for them to give their testimony it would raise the noblest of monuments to his memory.

Perkins was a most copious and attractive talker. In his earlier years he had a way of dropping in for a chat during the latter part of the evening. He was always a welcome guest, and with his cheery, vivid talk the time passed quickly. But soon the hands of the clock pointed to 1 a.m., and then to 2, and still the talk went on, until in justice to the coming day, the host—the hostess had molted away long before—had most reluctantly to dissolve the sitting. Most fluent talkers are egotists, but the noteworthy thing about Perkins's talk was his reticence about himself. It did not strike one as in the least degree egotistic, it was simply the reverse of egotism.

He was always a delicate man. During the past ten years he had at least four serious illnesses, two of which called for surgical intervention for a form of local tubercle. But through all this he always maintained his cheery aspect and never referred to his ailments, except, of course, when he was definitely asking advice about them. He never played any games, this was partly, no doubt, due to the disadvantage of having been brought up in a large town, but all through his life he was a man of the town and not of the country. He had no natural aptitude for games, and the delicacy of his constitution probably robbed him of the physical urge which might have made up for the deficiency.

Altogether he was a very lovable personality, and it will be long before his memory is lost.

Dr L S T BURRELL, physician to the Hospital for Diseases of the Chest, Brompton, writes:

Perkins was appointed assistant physician to Brompton in March, 1900, and in 1906 he became full physician. In 1921, after fifteen years on the full staff, he was granted a five years' extension, but in March, 1923, owing to failing health, he resigned, since when he has been consulting physician. During his time at Brompton he was extremely popular with patients and staff, and took a great personal interest in any new form of treatment, making a point of doing something for each individual patient and not treating them en masse. He was very keen on Trimpley Sanatorium, which he would frequently visit unofficially, and he made many suggestions for improvements. He endeared himself to the patients, who felt he took an interest in their whole lives, and he would sit on the foot of a bed and talk with a patient as a friend. Perkins had a very clear vision, and his advice was much sought by many friends, to whom he was always willing to give counsel. Personally, I shall miss his help greatly, for I never left him without feeling comforted and encouraged, and his death will leave a gap in a large circle of friends.

Dr E CHITTENDEN BRIDGES writes:

As an old friend of the late Dr J J Perkins, dating back some thirty-six years when we were appointed house-physicians at the Brompton Hospital for Diseases of the Chest, I feel I cannot refrain from adding my tribute to his memory. "J J," as he was affectionately known to all his old and intimate friends, was one of those strong personalities so seldom met with in this world, and this was associated with a most lovable nature which endeared him to all his many friends. He conducted his professional work according to the best traditions of the profession, which he guarded with pride and zeal, and he looked upon those who did not with scorn and ridicule. As a man who had made a special study of diseases of the chest he occupied a position in the profession second to none, his opinion was eagerly sought after, and he threw himself wholeheartedly into the work which he so thoroughly enjoyed and loved. If he had not been dogged by ill health for some years past he would have occupied a more prominent position in the profession. It was this continued ill health which wisely determined him to retire from consulting work a few years ago. Dr Perkins will be sadly missed by a very wide circle of friends, and the profession has lost a member who occupied it with dignity and honour. He has died respected and loved by all.

Dr J R A TOMMERTON (Knowle, Warwickshire) writes May 1 be allowed to add my humble tribute to the memory of Dr J J Perkins, whose tragic death has come as a great shock to all who knew him? I personally owed much to Dr Perkins, it was he who gave me my first lessons in clinical medicine, in the out-patient department at St Thomas's Hospital, and later I had the privilege of being his house-physician both at Brompton and at St Thomas's. To his juniors he was a cordial friend, and his shrewd advice was eagerly sought by, and readily given to, his old pupils, indeed, "See what J J P has to say about it" was almost a commonplace among us. I am sure that by all who were closely associated with him J J Perkins will be held in affectionate remembrance.

WILLIAM MACFIE CAMPBELL, M.D., C.M.,
Consulting Surgeon, Northern Hospital, Liverpool, Past President,
Liverpool Medical Institution

It is with much regret that we have to record the death of Dr W Macfie Campbell, which occurred after a brief illness at Birkenhead on September 14th, in his eighty-second year. Before his retirement some years ago he spent over forty years in practice in Liverpool, where he was intimately associated with the administration of the David Lewis Northern Hospital and played a leading part in the affairs of the Liverpool Medical Institution.

William Macfie Campbell, as his name at once suggests, was of Highland descent, he received his medical education at Edinburgh University, graduating M.B., C.M. in 1869, and proceeding M.D. in 1873, with a gold medal for his thesis. A year later he obtained the diploma M.R.C.S. Eng. After serving as house-surgeon at the Dreadnought Hospital at Greenwich Dr Campbell settled in Liverpool, where he built up a considerable practice. He was for some years honorary medical officer to the Liverpool Southern Dispensary, and at the time of his death was consulting surgeon to the Northern Hospital, on the committee of which institution he had served for many years. In early manhood he was associated with the Volunteer movement as medical officer to a Liverpool battalion, and had held office as president of the Liverpool Medical Institution. While his professional activities absorbed most of his attention, he found time to participate in educational work, and was also a justice of the peace for the city. Dr Campbell is survived by his widow, two daughters, and one son, Major Duncan Campbell, who is now chairman of the committee of the Northern Hospital, to which his father gave devoted service for many years.

A colleague, R W M'K, writes: Providence had endowed him richly. He was a king among men, in stature, in dignity of presence, in nobility of countenance, in intellectual gifts, and in the finer qualities of mind and heart. He had no ambitions either for wealth or place, he was content to do the day's work honestly. He helped every good cause that commended itself to him, and there was never any ostentation in his helpfulness. He "did good by stealth," encouraged in his altruism by that wise and gentle lady who was his loyal and understanding helpmate for so many years, and who is left to mourn him. The last few years of his life were years of suffering, but he bore his trials with quiet, unflinching bravery. He had lived on into an age when ancient landmarks have been removed and old beliefs thrown into the crucible. But, though he was alive to all these changes and keenly interested in modern speculations, he did not allow them to shake his quiet confidence. In his heart of hearts he preserved the faith of a little child.

Professor JOHN HAY (President of the Liverpool Medical Institution) writes: Others have ably voiced the more personal note in reference to the late Dr Macfie Campbell—a man who at one time had what was probably the largest practice in the south end of the city, and who was held in affectionate regard by all his patients. I should like to put on record an appreciation of the valuable work done by him for the profession in Liverpool, and more particularly for the Medical Institution—the most important centre of medical activity and interest in this city. In 1871 he

became a member, from 1875 until 1901 he was continuously in office, and during 1898 and 1899 he was President of the Institution. But, whether in office or out of office, he gave freely of his time and brains. He served the Medical Institution and the profession ungrudgingly, unselfishly, and wisely, and the vigorous health of our society at the present time is in no small measure due to his sustained efforts. He has left us a noble tradition of service.

Dr JOHN THOMLSON DUNLOP died on August 30th at his home in Newcastle-on-Tyne, at the comparatively early age of 66 years. He had a serious heart attack in August, 1927, and had been practically an invalid ever since, finally retiring from practice in May of this year. Dr Dunlop was a native of Boigne in Kirkcudbrightshire, where his father was rector of the academy there. He naturally gravitated to the University of Glasgow, and took the degrees of M.B. and C.M. in 1894. He went to Newcastle over thirty years ago, and built up a large general practice in the west end of the city. He was an honorary physician to the Hospital for Diseases of the Skin for over twenty years, and was on the staff of the Fleming Memorial Children's Hospital for the treatment of these diseases. During the war he was a member of the medical staff of the Northumberland War Hospital. Dr Dunlop found a congenial occupation as secretary of the Glasgow University Club in the North of England for the long period of twenty-five years, a post he resigned during his illness. His work was appreciated by his university and by his fellow members, and under his able guidance the annual dinner was always an intellectual and social success. His association with his patients was a happy blending of medical care and friendship, and he was greatly esteemed by them. He took his full share in the medical life of the city, was a member of the local executive of the British Medical Association, and a member of the Panel and Local Medical Committees. Any meeting for the furtherance of the social or medical life of the profession found in him a constant attender. To his fellow practitioners he was always a cheerful friend, and his genial presence will be sadly missed in the district. His funeral was largely attended by members of the profession.

Dr ALBERT WILSON, whose death took place at Fairwarp, near Uckfield on September 9th, had for many years devoted a large part of his time and thought to studies in criminology and was the author of a number of books and papers bearing on this subject. He was born in 1854 at Newcastle-on-Tyne, and received his early professional education at the University of Edinburgh, graduating M.B., C.M. in 1878, and proceeding M.D. (with gold medal for his thesis) in 1881. In 1879, when serving as house-surgeon to the Royal Infirmary, he held office as president of the Royal Medical Society of Edinburgh, and in the following year he was appointed resident physician to the Cowgate Dispensary. While a medical student he had spent many months in visits to clinics and laboratories in Paris, Berlin, Vienna, and St Petersburg, and became much interested in the psychological aspects of medicine. In 1890 Dr Wilson was appointed medical superintendent of the Essex County Asylum at Walthamstow, and after his retirement from that post he chiefly occupied himself in psychiatric practice and medico-sociological studies of criminal conduct in its relation to brain pattern and brain disease. The fruits of twenty-five years' work in this field were presented by him to the public in 1908 in a volume entitled *Education, Personality and Crime*. This book though readable and provocative of thought, and revealing deep sympathy with social misfits and congenital "wrong 'uns," inclined somewhat towards dogmatic statements on matters insusceptible of proof. A second volume, *Unfinished Man*, appeared in 1910, and he was engaged on another at the time of his death. During the war, although then past the age of 60, Dr Wilson served with the French Red Cross, and published papers on certain aspects of military medicine and surgery. He was a man of very generous instincts, whose innumerable acts of kindness were done in the most unobtrusive and self-effacing manner.

Dr EDWARD JOHN PARRY, who died on September 3rd in his seventy-eighth year, was one of the senior members of the medical profession in South Wales. He received his medical education in Edinburgh, obtaining the diplomas L.R.C.P. and L.R.C.S. Edin in 1878, and graduating M.D.R.U.I. two years later. His professional life was spent almost entirely in Glamorganshire, and he became, soon after commencing practice, principal medical officer to the Garw Valley collieries, an appointment which he held until 1916. During the war Dr Parry, who was a member of the British Medical Association, served as chairman of the county medical recruiting board. He took an active part in public affairs and was a member of the first county council elected in Glamorgan, serving also on several other public bodies and being one of the senior magistrates for the county. A keen supporter of the Liberal party in politics, he was for many years president of the Mid Glamorgan Liberal Association, efforts to induce him to become a candidate for Parliament were, however, unavailing. Dr Parry gave himself freely to the service of the miners among whom his work lay, and was a generous friend to any movement designed to advance their welfare notably in the promotion of efforts to secure the advantages of higher education for the miners' children.

The following well-known foreign medical men have recently died: Dr VINCENZO DE GRAZIA, formerly professor of hygiene at Pisa University, Dr F. ALOR, professor of medical chemistry at the Toulouse Faculty of Medicine, and corresponding member of the Académie de Médecine, Dr LAGRANGE, honorary professor of clinical ophthalmology at the Bordeaux Faculty of Medicine, corresponding member of the Institut de France and Académie de Médecine, and Commander of the Legion of Honour, Dr MANO LANDOLT, president of the French Society of Ophthalmology, Dr CABANES, the prolific and entertaining writer on the curiosities of medical history, and editor of *La Chronique Médicale*, aged 60, Dr GIOVANNI DI CRISTINA, professor of clinical pediatrics at Palermo, and author of numerous articles on splenic anaemia, chloroma, leishmaniasis, and the etiology of scarlet fever and measles, aged 52, Professor FERNANDEZ FIGUEIRA, an eminent paediatricist of Rio de Janeiro, and Professor STANKOW, a Riga anatomist, aged 54.

Universities and Colleges

ROYAL COLLEGE OF SURGEONS OF ENGLAND

DEMONSTRATIONS

THE autumn course of demonstrations of specimens in the Museum will be given in the theatre of the College, Lincoln's Inn Fields, W.C. will commence on Friday, October 19th, when Sir Arthur Keith will deal with the problems of human anatomy which arise out of the identification of a skull attributed to Lord Darnley (see *British Medical Journal* September 8th p. 456 and September 15th, p. 505). On October 26th and November 2nd he will discuss the development of the human foot and its bearings on club foot and other orthopaedic disorders. Demonstrations of surgical specimens will be given by Mr T. W. Lawrence on October 22nd and 29th and November 5th. The demonstrations, which are open to advanced students and medical practitioners, commence at 5 p.m.

Medical News.

THE inaugural address at the Westminster Hospital Medical School will be given by Mr A. C. Powell, M.A. (headmaster of Epsom College) in the board room of the hospital on Monday, October 1st, at 3 p.m. The chair will be taken by Sir William Goschen, K.B.E. The annual dinner of past and present students of Westminster Hospital will be held in the Royal Adelaide Galleries, Gatti's Restaurant, on the evening of the same day, at 7.30 o'clock, with Sir James Purves Stewart in the chair.

THE annual dinner of the Chelsea Clinical Society will be held at the Hotel Rombrandt, Tharloe Place, on Tuesday, October 23rd at 7.30 p.m. Members are asked to inform Mr L. A. Harwood (90, Sloane Street, S.W.1) as early as possible of their intention to be present and the number of their guests.

THE winter session, 1928-29, at University College Hospital Medical School opens on Monday, October 1st, when an introductory address will be delivered in the Library by Sir Thomas Barlow, Bt, M.D., F.R.S., at 4.30 p.m.

THE annual general meeting of the Medical Sickness, Annuity, and Life Assurance Society will be held at the First Avenue Hotel, High Holborn, W.C.1, on Monday, October 8th, at 4 p.m.

THE Fellowship of Medicine and Post Graduate Medical Association announces that a series of four lecture demonstrations in electrotherapy will be given by Dr C. B. Heald at the Royal Free Hospital at 5.15 p.m. on Wednesdays, beginning on September 26th. There will be an all day course in diseases of the throat, nose, and ear at the Central London Throat, Nose and Ear Hospital from October 8th to 26th, the clinical course, operative class, or pathology class may be taken separately. Courses will be given at the Chelsea Hospital for Women in gynaecology, from October 8th to 20th, at the London School of Hygiene and Tropical Medicine in tropical medicine, on Tuesday and Thursday afternoons from October 9th to November 1st, at the Hospital for Sick Children, Great Ormond Street, from October 15th to 27th. At the Royal Free Hospital Professor Louise McIlroy will give four lecture demonstrations in ante-natal treatment on Fridays at 5 p.m., from October 26th to November 16th. There will also be weekly clinical demonstrations at various hospitals in medicine, in surgery, and in ophthalmology, and a weekly demonstration at the Wellcome Museum of Medical Science. Syllabuses are obtainable from the Fellowship of Medicine, 1, Wimpole Street, London W.1.

THIS year's Galton Lecture, which was given by Mr C. J. Boud, and was entitled "Some Causes of Renal Decay," has been printed as one of the People's League of Health pamphlets, with the permission of the Engelen Society. It can be obtained from the Secretary of the People's League of Health, 12, Stratford Place, W.1, price 6d. We gave some account of this Galton Lecture in our issue of February 25th (p. 315).

THE number of convictions for drunkenness in England and Wales in 1927, as shown in the recently issued Home Office *Licensing Statistics* for that year, was 65,166—a decrease on the previous year of 1,960, or 2.9 per cent—this being the lowest since 1919. A decrease was also recorded in the number of on-licences for the sale of intoxicating liquors, and it is shown that there has been a sustained fall in the number of on-licences in proportion to population over a prolonged period. At the beginning of 1908 there were 27,244 on-licences per 10,000 of the population and at the beginning of 1927 there were no more than 20.19 on-licences per 10,000 of the population. It is stated in the report that to some extent a better distribution of licences is to be preferred to a mere reduction in the number. Convictions for drunkenness due to the consumption of methylated spirits have increased by 10 per cent—from 389 in 1906 to 428 last year. Under Section 40 of the Criminal Justice Act, 1925, which came into operation at midsummer, 1926, 1,438 persons were in 1927 convicted of drunkenness while in charge of mechanically propelled vehicles, and were disqualified for twelve months from holding a motor driver's licence. The number in the second half of 1926 was 804.

MESSRS EDWARD ARNOLD and Co. announce for early publication *Modern Problems in Neurology*, by S. A. Kinnier Wilson, M.D., and a *Text Book of Surgical Diagnosis*, in two volumes, edited by A. J. Walton, F.R.C.S.

THE total diphtheria death rate in 1927 in the large cities of the United States was higher than in either of the two preceding years. From 1923 to 1926 inclusive the total diphtheria death rate in these cities had fallen regularly every year. In all European countries also the incidence of diphtheria was unusually high in the winter of 1927-28, and in Italy and Poland it was higher than at any time during the past five years.

THE thirteenth French Congress of Legal Medicine will be held at the Paris Faculty of Medicine, under the presidency of Dr Georges Brouardel, from October 9th to 11th, when the following subjects among others will be discussed: expert evidence in social questions, introduced by Professor Balthazar; industrial accidents, comparative results of external methods and osteosynthesis in the treatment of fractures of the leg, introduced by MM. Charbonnel and Massé of Bordeaux; professional intoxication by hydrocarbons, introduced by M. Duvour of Paris; and social reactions in epidemic encephalitis, introduced by M. Fribourg-Blauc of Paris. The subscription is 60 francs. Further information can be obtained from Dr Piéchéllèvre, 24 Rue Gay-Lussac, Paris.

IN 1927 only four cases of small pox occurred in Germany. These had all been introduced from foreign countries. In the same year no fewer than 14,800 cases were notified in England and Wales.

DR ALBERT R COOK, senior physician to the Munga Hospital of the Church Missionary Society and consulting physician to the Government European Hospital, Kampala, has been awarded the silver medal of the African Society in recognition of his work in Africa. Dr Cook has in thirty-two years built up a highly efficient and extensive medical mission among the people of Uganda.

THE Department of Scientific and Industrial Research has published the thirteenth report on the investigation of atmospheric pollution (obtainable from H M Stationery Office, London, or through any bookseller), dealing with observations in the year ended March 31st, 1927, this is in continuation of the series of reports of the Advisory Committee on Atmospheric Pollution, hitherto issued by the Meteorological Office, the change following upon the transfer to the Department of Scientific and Industrial Research of responsibility for the Government's share in the work. The Advisory Committee will become a standing conference of co-operating bodies. In the report the deposit of impurity at 80 different stations in the United Kingdom is considered, a classification is made according to standards of increasing quantity of deposit, this being denoted by the letters A to D in order of quantity of pollution. It is satisfactory to note that there has been a substantial improvement in atmospheric purity in the areas covered, in 1914-15 the number of stations ranking as A and B was 54 per cent of the total, in the year under review the number was 87 per cent of the total. A steady decrease in the quantity of sulphates deposited in London and Glasgow has been observed, and it is stated that this, at least in part, due to the increasing use of coal gas, this having presumably replaced raw coal. The tables included in the report give details month by month of the deposits collected at the various stations, showing wide variations in their composition. A section dealing with suspended smoky matter in the air illustrates the effect of the coal stoppage of 1926, while the obstruction of ultra violet radiation by smoke is brought out by a curve which indicates that nearly the whole of the ultra violet rays is cut off by a comparatively small amount of smoke in the air. Much of the matter contained in this slim volume—it contains less than sixty pages—is of considerable scientific interest and should be of some practical value to those engaged in public health work, but its publication at the net price of 6s 6d will not encourage a wide circulation.

THE Commonwealth Department of Health (Central Office) will be transferred from Melbourne to Canberra, the federal capital of Australia (Federal Capital Territory), as from October 1st, 1928.

THE twenty-fifth anniversary of the foundation of the German Institute for Investigation of Cancer, which is attached to the Charité Hospital in Berlin, was recently celebrated by a special meeting under the presidency of Professor Friedrich Kraus.

SIX series of post-graduate courses in English will be held in Paris under the supervision of the University medical school, in most cases these are associated with practical work. Ten lectures on diseases of the bronchi, with pathological and radiological demonstrations, will be given by Professor Sergent, at the Charité Hospital, from October 29th to November 3rd. A course of nine lectures on diseases of the heart and vessels will be given by Dr Clerc, at the Lariboisière Hospital from October 20th to 30th. Dr Armand Dailly and Dr Weill Hailo will hold a course in diseases of children from October 8th to 20th at the Charité Hospital, and Professor Gossset will give a five day course on surgery of the digestive tract and liver, with operative demonstrations and operations on the dog, at the Salpêtrière Hospital, commencing on October 15th. Drs Morax and Lemaître will conduct courses in ophthalmology and oto-rhino-laryngology covering the period from October 2nd to 26th. Further information and detailed programmes may be obtained from the secretary of the Association pour le Développement des Relations Médicales, Salle Bechard, Faculté de Médecine, 12, Rue de l'Ecole de Médecine, Paris VI.

THE following appointments have recently been made in foreign faculties of medicine. Professor G. Katoch of Frankfurt, professor of internal medicine at Großwald in succession to Professor Stranb, Dr L. Kumor of Vienna, professor of dermatology and venereal diseases at Innsbruck. Dr Alfred Link of Königsberg, professor of oto-rhino-laryngology at Großwald, and Dr Luiz Barbosa, professor of clinical pediatrics and infantile hygiene at Rio de Janeiro, in succession to the late Professor Nascimento.

THE proceedings of the thirteenth Congress of Medicine of Northern Countries, held at Copenhagen under the presidency of Professor V. Bie have recently been published as a special supplement to *Acta Medica Scandinavica*, under the editorship of Dr A. Norgaard, the general secretary, the communications appearing in English, French, and German.

Letters, Notes, and Answers.

All communications in regard to editorial business should be addressed to **The EDITOR, British Medical Journal, British Medical Association House, Tavistock Square, W C 1**.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the **BRITISH MEDICAL JOURNAL** alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names, not necessarily for publication.

Authors desiring REPRINTS of their articles published in the **BRITISH MEDICAL JOURNAL** must communicate with the Financial Secretary and Business Manager, **British Medical Association House, Tavistock Square, W C 1**, on receipt of proofs.

All communications with reference to ADVERTISEMENTS as well as orders for copies of the **JOURNAL**, should be addressed to the Financial Secretary and Business Manager.

THE TELEPHONE NUMBERS of the **British Medical Association** and the **British Medical Journal** are **ML 5611 9561 9562 9363**, and **3561** (internal exchange four lines).

THE GRAPHIC ADDRESSES are
EDITOR of the **British Medical Journal** *Antiology Westcott, London*

FINANCIAL SECRETARY AND BUSINESS MANAGER
(Advertisements etc.) *Antiology Westcott London*
MEDICAL SECRETARY *Medicera Westcott London*

The address of the Irish Office of the **British Medical Association** is 16 South Frederick Street, Dublin (telegram *Beallus Dublin* telephone 62550 Dublin) and of the Scottish Office 7 Drumshough Gardens, Edinburgh (telegram *Associate, Edinburgh* telephone 24361 Edinburgh).

QUERIES AND ANSWERS.

DIFT IN "GALLSTONE DYSPEPSIA"

"**LOCUM**" writes: I shall be grateful if one of your readers will prescribe a suitable dietary for a patient suffering from gallstone dyspepsia. He has been operated on several times and his symptoms are now supposed to be due to adhesions in the neighbourhood of the duodenum.

CONS.

"**W J B S**" writes: In further reply to "**H A A**" (*Jan 14th*, p. 85), I use the antiseptic cannibus India corn plaster, covered again by a larger piece of adhesive plaster. This sets up a positive action. The application should be renewed each day, removing the epidermis that has been softened. In the case of an ordinary corn the corn usually comes out after the first day.

TREATMENT OF COLI BACILLURIA.

DR GEORGE WILLYTT (Barnstaple, Bristol) writes: In reply to the inquiry by "**J M S**" (September 15th, p. 513) I suggest the trial of mercurochrome bladder washes and, failing that, one of silver nitrate. As the urine is constantly acid perhaps it might help matters if, for the time, it was rendered alkaline as *B. coli* flourish in both an acid and an alkaline medium. Possibly the presence in the urine of crystals of calcium oxalate may explain part at least of the general condition and the headache.

"**P T J**" writes: I have recently had a very stubborn case of *B. coli* infection of kidney and bladder and have obtained two consecutive negative cultures at two months interval from the use of acriflavine Messrs. Bools (Nottingham) have made a tablet of this drug otherwise so inconvenient to administer, which my patient has been able to take regularly.

DR A. A. BISSET (Harrogate) writes: If treatment by intestinal douches has not been already tried they might diminish the bacilluria. Many cases of coli bacilluria show mucous colitis and swelling of the right kidney. Intestinal douches properly administered over a period of three to four weeks in most cases effect a cure. A diet containing a large amount of vitamin B is also a valuable adjunct to treatment.

"**F H E**" writes: I suggest that "**J M S**" employ mercurochrome. One ounce of a 1 per cent solution is used. The patient is put to bed. The bladder is emptied by a No. 10 catheter to which a tube and funnel are attached. The funnel is then raised and the warmed mercurochrome solution allowed to trickle in. No pain is caused. The solution is retained for half an hour. A second application is rarely necessary—perhaps in one case out of five.

VAGINITIS.

"**G L**" writes in reply to "**G A**" (September 8th p. 473). My answer is (1) Consult a gynaecologist. (2) do not resort to psychotherapy. "**G A**" states that the vagina has been twice stretched without result but he has not carried out the essential after treatment which consists in passing a vaginal dilator and showing the patient how to pass it on herself.

"**G P**" writes: I had a similar case some time ago. The vaginismus readily responded to vaseline and cocaine, smeared on to the vulva by the patient herself.

INCOME TAX

Use of Residence, Book Debts

"N II" explains that his house was acquired solely for professional use and that his family live elsewhere. Separate waiting rooms are used for private and panel patients, and one bedroom is set aside for the use of patients. He also inquires as to the necessity for bringing into the account outstanding professional book debts.

"* * It certainly seems that 'N II' uses his house for professional purposes to a greater extent than usual, and we think he should press for the allowance of two thirds of the rent rates etc. With regard to the book debts, 'N II' cannot legally claim to be assessed on the basis of cash receipts only, but a deduction should be made in respect of the debts—or portions of debts—that are considered to be irrecoverable. The dictionary definition of 'earn' does not really help the legal argument. It is settled law that the probable value of fees obtainable but not received must be brought into the income tax computation."

Expense of Indoor Assistants

"T M" employs two qualified indoor assistants. How much can he regard as expended by him on their maintenance? The inspector of taxes considers £100 each adequate, but the previous inspector allowed £250 for one assistant.

"* * Circumstances vary so much that it is impossible to lay down any definite guidance. If the £100 each is to cover share of rent and rates and domestic service, laundry etc., it hardly seems enough. Actual food costs can, no doubt, be estimated fairly closely by Mrs. 'T M'."

LETTERS, NOTES, ETC.

MEDICAL EDUCATIONAL WORK

Mr KENNETH WALKER F.R.C.S. and Dr A. H. HARKNESS (honorary medical secretaries of the British Social Hygiene Council) write: "Owing to the growing work of this council it has been found necessary to obtain the services of a whole time salaried medical secretary who is able to undertake medical educational work in connection with the general organization of the council in all parts of the country. The work of the medical department is under the direction of the honorary medical secretaries and the medical advisory board. The medical secretary would also give assistance in the general work of the council. As this entails a considerable amount of public speaking preference will be given to those accustomed to handling both medical and lay audiences. The post would give scope for anyone interested in research on venereal subjects and would probably be suitable for a younger man retired from one of the Services. [Further particulars are given in our advertisement columns]."

TREATMENT OF WHITLOW BY X RAYS

Dr W. J. B. BURKE (Bordeaux) refers to the remark by Dr A. A. Masser on September 24th, 1927 (p. 573) that he had been unable to find any reference in the literature to the therapeutic action of x rays in septic or inflammatory conditions. Dr Burke writes: "As I have had some experience of this method of treatment I wish to record a few observations. In 1907 an English lady in Manila consulted me for a whitlow in the right middle finger. The finger was considerably swollen, two or three red streaks were visible on the forearm and arm and a gland was palpable in the axilla. I made a small incision in the pulp of the finger and, after evacuating the pus, I applied x rays for ten minutes to the finger and then dressed the small incision antiseptically. The next day I applied the x rays to the bend of the elbow, the forearm being slightly flexed, hoping that the arm and forearm would thus benefit by the application. The rays were again applied to the finger on the third day and on the fourth to the arm and forearm. No application was made on the fifth day, but on the sixth the rays were again applied to the finger. Meanwhile the wound was dressed only once daily. The patient made a complete recovery. Being struck by the success of the treatment I looked up the literature and found that others had already used a similar method. Thus Pfahler (*Amer. Journ. Med. Sci.* April, 1906) reported one case of chronic paronychia onychitis cured by x ray application and Pellizzari had three cases cured in a similar manner (*Sem. Med.* January 28th 1907). The interest attached to the above case is the small amount of attention the incision required and further its small size, which was only about 1/4 in. in length. In 1919 I treated also in Manila a Spanish lady on the same lines. Here however I could not arrest the suppuration though all acute inflammation ceased in about six days. The small incision continued to suppurate for three weeks. I then probed the wound and found necrosed bone. A day or two later on making pressure on both sides of the incision, a small fragment of necrosed bone protruded and I was able to pick it out with a dressing forceps. The wound healed a few days afterwards. In 1925 I had a whitlow on the left middle finger but as I was very busy I neglected it. On the third night the pain was very severe, the whole finger had become much swollen, a red streak was present on the forearm and an axillary gland was palpable. I applied x rays over the bend of the elbow, the forearm being slightly flexed for ten minutes and then on the pulp of the finger also for ten minutes. The next day there was considerable improvement, and no further applications were required. I applied once daily 10 per cent. guaiacol in vaseline over the

whitlow. Improvement started after the x ray applications, the inflammation began to subside and in a few days the skin at the base of the nail opened spontaneously, a slight purulent discharge escaping. There was no further trouble. I do not think it was the guaiacol which effected the cure. I tried it afterwards in boils and furuncles but found the inflammatory processes were not arrested by its application."

TREATMENT OF MILD MENTAL DISORDER

Dr S. E. WHITE (Manor Park, E.) writes: "By having recourse to a common sense expedient doctors could avoid placing themselves in the predicament of having to certify doubtful cases of mental instability, with its attending risk to themselves. Such a course is in many instances forced upon them unwillingly because at the present time there exists no alternative. Let the medical profession make up its mind without delay to advocate the provision of hostels without detention and free from any link with lunacy, to be run by health committees and to serve as an alternative to asylums, for the benefit of those who cannot be proved to be dangerous or unfit to be at large. Such a provision was advocated by the Council of the British Medical Association (see *Supplement*, April 28th p. 169) where reference was made to patients with mental disorder who 'do not either in their own interests or in the interests of the public, require compulsory restriction of their liberty' and ought not to be brought before the jurisdiction of the Board of Control. The existing provision for treatment of this order especially for poorer patients, is quite inadequate and ought to be increased. Where an expedient of this nature has been tried it has proved an excellent preventive of insanity, and would in a short time justify itself in a very large reduction in the eight millions per annum now spent upon mental institutions. Pressure ought to be brought to bear upon the Government in this direction by the medical profession for not only would doctors find it an immense relief to have places to which to recommend their patients to go voluntarily, without having to undertake the unpleasant task of certifying, but the places would also prove an untold boon to the community. No legislation is needed, for the Public Health Act, 1875, gives power to borough councils to run such hospitals."

FORCE'S DELIVERY OF IMPACTED BREAST

Dr. I. H. FARM (Birmingham) writes: "I desire to report a case of impacted breast which I delivered successfully with the aid of forceps. The patient was a primipara, aged 29. When I received the message from the midwife the membranes had ruptured some hours previously but the os was not fully dilated. McConium was being passed in large quantities at frequent intervals. The patient was a strong robust woman and the pains were frequent and strong, yet there was no advance of the buttocks, even after full dilatation and a delay of more than one hour. I eventually anesthetized her and with the nurse pressing firmly on the fundus I applied forceps and delivered a live male child weighing about 10 lb."

HERPES AND VARICELLA

Dr S. WAND (Birmingham) writes: "I have read with interest Dr Hill's article (August 4th, p. 197) on the ever recurring question of the association between varicella and herpes. Although I can show no statistics my own experience brings out the following salient points: (1) I have never seen a patient with herpes infect another with herpes. (2) In a varicella epidemic adults (especially those who have had varicella) develop herpes and children varicella. (3) Much more rarely a case of herpes seems to infect with varicella. It is difficult in such cases to decide whether a case of herpes or varicella is the causative factor, as they usually occur during a varicella epidemic."

CHRISTIAN SCIENCE AND THE DOCTOR

Mr CHARLES W. J. TENANT (London W.C.2) writes: "To make statements about prominent people accompanied by the semblance of a foundation of fact is a well known form of hostile propaganda and from the article in the *British Medical Journal* of September 15th (p. 533) I observe that you have received some of the 'anti Christian Science literature' which is being circulated at the present time. The senders of the literature in question are not so much concerned in forming a church of question as in attacking Mrs. Eddy, the discoverer and founder of Christian Science, and the Church of Christ Scientist which she founded more than fifty years ago. Christian Science is a religion and the latest form of attack is regarded by Christian Scientists as only an invitation to them to cease to live and practise it. The situation among Christian Scientists is very different to that described in the article. There is no schism in the Church, nor is there any 'heresy hunt' going on among its members. May I add that Mrs. Eddy's life was always consistent with her writings, and the truth about her is to be found in them?"

HAEMOPHILIA AND DENTAL EXTRACTION

The name of the author of the first note published under the above heading in the *Journal* of July 28th (p. 182) was Mr A. S. V. Daniels, L.D.S., R.C.S. Eng. and not as stated in that issue.

VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals will be found at pages 43, 44, 45, 48, 49, and 50 of our advertisement columns, and advertisements as to partnerships, assistantships, and locum tenencies at pages 46 and 47. A short summary of vacant posts notified in the advertisement columns appears in the *Supplement* at page 140.

An Address

63

THE BACTERIAL FLORA OF THE INTESTINE IN HEALTH AND IN CHRONIC DISEASE*

BY

JOHN CRUICKSHANK, M.D.,

Professor of Bacteriology, Marischal College, Aberdeen

In opening this discussion it is my intention to give a brief review of our knowledge of intestinal bacteria, to discuss the subject in general, and to omit as far as is possible technical matter of laboratory nature. The bacterial flora of the intestine of the adult is extremely complicated, and I think it may be approached most easily by a study of the development of these organisms in the infant. In the newly born infant the meconium is sterile, but organisms appear in small numbers within the first twenty-four hours. During the first few days the organisms most frequently found are *Staphylococcus albus*, *Streptococcus faecalis*, and members of the *Bacillus coli* group. With the first sample of meconium free faeces short, slender, Gram-positive bacilli appear, to which Tissier gave the name *Bacillus bifidus*. In the next few days there is a rapid increase in these organisms and a diminution in the coliform and other organisms until a film of the stool shows practically no other bacteria, although by cultural methods coliform organisms, streptococci, staphylococci, and spore-bearing organisms can be shown to be present in small numbers. So long as breast-feeding is the only means of nourishment the bacterial flora of the infant's faeces is predominantly of the *B. bifidus* type, 95 per cent of the organisms in a film being of this type. The flora of infants who are artificially fed shows greater complexity, and the predominant organisms are of coliform type. Streptococci are found in greater numbers than in the suckling's stool, and spore-bearing organisms are present in most cases.

The faeces of breast-fed infants are always distinctly acid in reaction, whereas the stools of the artificially fed children are alkaline or neutral. This difference in reaction of the stools of the breast-fed infant and those of the artificially fed is of considerable importance in relation to the types of bacterial flora. The alkalinity of the faeces of infants fed on cow's milk has been attributed by Miller to the action of putrefactive bacteria on the large amount of protein which is present in cow's milk as compared with human milk, while Schlossmann believes that the important factor is the protein fat ratio. The acidity of the suckling's stool has been attributed to the high content of lactose in the breast milk, and it has been shown experimentally that the addition of lactose to the dietary of rats results in highly acid contents of the caecum, whereas a high protein diet does not produce this. Clark and Marriott have suggested that the poverty of human milk in buffer salts allows of a rapid change in the reaction, and the acids produced are free to act upon the intestinal mucus causing a rapid evacuation of the contents and an acid stool. In support of this is the observation that in diarrhoeal conditions the stools are usually acid as compared with normal. It has been established that *B. bifidus* and related organisms of the *B. acidophilus* type can survive exposure to highly acid fluids which destroy coliform organisms, and the predominance of these organisms in the stool of the breast-fed infant and the poverty in coliform organisms has been attributed to the acid reaction of the intestinal contents. The absence of spore-bearing organisms in the suckling's stool is attributed to the same factor, and it has been shown that the growth of these organisms is markedly inhibited in highly acid media in which *B. bifidus* and *B. acidophilus* survive. Some workers, however, are of opinion that the acid-resistant organisms are directly antagonistic to the growth of *B. coli* and the spore-bearing anaerobes.

After the period of breast-feeding the child is quickly introduced to a variety of foodstuffs, and during adolescence and adult life many kinds of proteins and carbohydrates are ingested. Opportunity is offered for the invasion of the alimentary tract by many organisms, and the bacterial flora of the intestine becomes correspondingly complicated. The nature of the diet, the habits of the individual, particularly as regards the evacuation of the bowels, and the degree of physiological balance of the numerous intestinal ferments all affect the flora. From the bacteriological aspect great difficulties present themselves in any attempt to determine the variety of organisms contained in any one sample, and the quantitative relationships of the various types are almost impossible to determine. The majority of the organisms are facultative anaerobes and possess a wide range of saccharolytic and proteolytic activities. To isolate even a few types a considerable variety of media must be used, as the growth of one species frequently exerts an inhibitory effect on the development of others. For example, plating out on agar or similar medium gives abundant growth only of certain types of coliform organisms and streptococci. Some organisms—for example, *B. acidophilus*—can be obtained only by the use of media which prevent the growth of the coliform organisms. The use of liquid media for primary culture results in overgrowth of one or more types and suppression of others, giving a false picture, particularly of the quantitative relationship. To obtain even a partial picture a great variety of media must be used, anaerobic methods of culture adopted, spore-bearing organisms specially provided for, and the examination of one sample of stool may require many days of work.

To simplify the results for clinical purposes it has become usual to group the intestinal organisms into two types—proteolytic and saccharolytic. This division is based primarily upon the study of the organisms in the stool of the infant, the flora of the breast-fed being regarded as saccharolytic in type, while that of the artificially fed is regarded as proteolytic. Horter and Kendal first attempted to obtain a correlation between the types of intestinal bacteria and the chemical composition of the food in experimental animals. In experiments on monkeys and cats it was found that a high carbohydrate diet, especially milk and lactose, gave a flora rich in *B. bifidus* and *B. acidophilus*, whereas a high protein diet (meat and eggs) gave a predominance of coliform organisms and spore-bearers. Hall and Rettger extended these experiments to the examination of a series of common carbohydrates, and showed that lactose was the only one with the power to transform the flora to the saccharolytic type. Distaso and Schiller found that dextrin also was efficient.

The results with lactose seemed to support the theory that in the suckling infant the determining factor in the production of the saccharolytic type of flora was the lactose. Sittler in 1908 had found that the addition of lactose to cow's milk transformed the proteolytic flora of the artificially fed infant so that it approached that of the suckling in type, whereas the addition of saccharose had no effect. In 1915 Torrey reported favourably upon the use of lactose in the treatment of cases of typhoid fever, a most marked change occurring in the bacterial flora with almost entire elimination of the obligate anaerobes. The change to the saccharolytic type of flora was more difficult when the initial flora was markedly proteolytic, but was of quite radical nature when the initial flora was of more simple type. As a result of lactose feeding the cases ran a milder course, with less alimentary disturbance and few complications. In 1919 Morris, Porter, and Moyer applied similar high carbohydrate diets with success to the treatment of children suffering from a clinical syndrome characterized by lassitude, constipation or diarrhoea, anorexia, and stupor. The condition was associated with a marked proteolytic or putrefactive intestinal flora, and the improvement in the clinical condition was always found to be associated with a change in the flora to the saccharolytic type. A quicker transformation of the flora is achieved by combining lactose diets with cultures of acidophilus organisms. The strains of *B. acidophilus* used must be capable of surviving in the human intestine, and should preferably have been obtained from this source.

* Given in opening a discussion in the Section of Pathology and Bacteriology at the Annual Meeting of the British Medical Association, Cardiff 1928.

Cultures of the organism in milk give the best results. Rettger and Cheplin in 1921 compared the effect of lactose alone (300 grams), lactose (150 grams) and emulsions of *B. acidophilus*, and *B. acidophilus* milk (500 to 1,000 c cm) in six human adults. In each case there was a complete transformation of the flora to the saccharolytic type. Beneficial results in the treatment of constipation and of diarrhoea in children and adults by the use of *acidophilus* cultures, with or without lactose, have been reported by numerous clinicians. As a result of treatment there is a marked diminution in the numbers of *B. coli* and almost complete elimination of putrefactive anaerobes and other proteolytic organisms. It should be noted that large volumes of *acidophilus* milk and lactose are required to effect the transformation, and that the bacterial flora reverts quickly to the ordinary type on cessation of treatment.

From the bacteriological aspect there are several points of interest in the above experiments. The effect of the lactose is generally attributed to slow absorption in the intestines, so that fermentation occurs in the lower levels of the intestines by the action of saccharolytic organisms with the production of a high degree of acidity, diminution of *B. coli*, and development of acid-resistant (aciduric) organisms of the *B. acidophilus* type. It has, however, been shown that the administration of lactose causes a rise in blood sugar which is comparable to that obtained with glucose, but which is a little delayed. It would appear, therefore, that amounts of lactose such as are employed in blood sugar tests are absorbed comparatively quickly, and that the theory of slow absorption of lactose probably only holds for large amounts of this substance. The great majority of coliform organisms ferment lactose readily, and in the presence of both protein and carbohydrate the latter is always first attacked. In the examination of pure cultures of many strains of *B. acidophilus* isolated from human faeces I have found that these organisms are, in general, very weak fermenters of carbohydrates, and it is difficult to correlate these findings with the view that lactose is primarily attacked by these organisms so that a degree of acidity of the intestinal contents develops which is inimical to the development of *B. coli*, and may even cause suppression of the organisms. It would seem to me more probable that the lactose is attacked by *B. coli* and *B. welchii*, and that the various acid substances produced by such fermentation offer a suitable pabulum in which *B. acidophilus* rapidly develops. This is suggested by our experience that the direct inoculation of faeces into milk gives abundant growth of *B. coli* and enterococci in the first few days, but that at a later date vigorous growth of *B. acidophilus* occurs and that a pure culture of the latter may be obtained after seven to ten days' incubation. In recent years many experiments have been made on dogs and rats which demonstrate the transformation of the faecal flora to the saccharolytic or *acidophilus* type by the addition of lactose or dextrin to the diet and the maintenance of this flora so long as the diet is continued. The administration of glucose, saccharose, and maltose is associated with an increase only in the numbers of streptococci. Starchy foods, particularly potatoes, white bread, and beans, also tend to change the flora.

The administration of animal proteins, on the other hand, produces a markedly proteolytic or "putrefactive" flora. According to Kendall and Hamer the saccharolytic organisms are *B. acidophilus*, *B. bifidus*, *B. welchii*, and enterococci. The conditions in the intestine which favour the production of these organisms are more favourable to the development of acid-resistant (aciduric) organisms than to *B. welchii* and the enterococci, so that these are overgrown and appear in the faeces only in small numbers. Among the proteolytic organisms which may be present in the intestine are *B. sporogenes*, *B. putrificus*, *B. mesentericus*, *B. proteus*, and *B. pyocyaneus*. *B. coli* has both saccharolytic and proteolytic activities, but it is present in greater numbers in faeces of the proteolytic type. It has not been possible to correlate the activities of these organisms when tested in pure culture with the pictures obtained in dietetic experiments. There has therefore been an increasing tendency on the part of bacteriologists to devise methods by which the activities of the mixed

organisms of a sample of stool could be determined without consideration of the activities of each member after isolation in pure culture. In short, the methods employed are intended to give a broad distinction between saccharolytic and proteolytic type of flora.

I have dealt with the feeding experiments at some length, as they seem to me to show some advance in recent years in our knowledge of the influence of diet on the flora of the intestinal canal, and of the relation which appears to exist between the two broad types of flora and certain conditions of constipation and diarrhoea. I have repeated many of the feeding experiments on rats, and find the results substantially correct. The experiments on animals and on man show clearly that in order to change the intestinal flora to the "aciduric" type large amounts of lactose must be given combined with considerable volumes of a milk culture of a strain of *B. acidophilus* which has been shown to be capable of survival and growth in the human intestine. Metchnikoff's sour milk treatment was a failure because the organism which he used was not one which could survive in the human intestinal tract. Small amounts of culture of *acidophilus* organisms, either in the dried form or in the form of an emulsion such as is supplied by many firms for the treatment of human diseases, are practically useless. The literature on this subject conveys the impression that the proteolytic or "putrefactive" flora, because it is frequently associated with disturbed conditions of the intestine, is in itself harmful, but it should be remembered that the bacterial flora of the ordinary individual on the most varied of common diets tends strongly to be of proteolytic nature, and that in the diet of adults lactose and dextrin are almost absent. The types of intestinal flora are most probably the result of the abnormal intestinal conditions—not the cause of them.

The term "putrefactive flora" suggests the production in the intestine of poisonous substances, and immediately raises the subject of intestinal auto-intoxication. Alimentary toxæmia has been the subject of so much work in the past that I do not intend to make more than a brief reference to it. In the years which have elapsed since intestinal auto-intoxication or alimentary toxæmia was discussed by no fewer than fifty six speakers at the meeting of the Royal Society of Medicine in 1913, nothing has emerged from experimental chemical or bacteriological work which has given any support to the view that, as the result of bacterial action in the intestine, poisonous substances are elaborated, which by their entry into the tissues of the body, produce chronic intoxication. A complete and critical review of this wide subject has been made in recent years by Alvarez. Certain experimental work bearing on the subject of acute intestinal obstruction has been carried out, the results of which are important in the consideration of subacute and chronic disorders of the intestine. It has been clearly proved by Brook and Murphy, Hartwell and his associates, and confirmed by Dragstedt and others, that in complete obstruction of the intestine the intact intestinal mucosa presents an almost impassable barrier to the products of bacterial action within the closed loop. The closed loop of intestine contains, as a result of bacterial action, substances which are extremely toxic when administered parenterally, but these are incapable of doing harm until the intestinal mucosa is grossly damaged, particularly in its vascular relationships. A considerable loop of intestine may be tied off, but, provided that the circulation above and below the loop is established, the animal may remain in good health, although the loop contains extremely poisonous and diffusible substances, until, as a result of distension, the vascular supply to the mucosa is cut off, when absorption rapidly occurs or perforation results.

Dragstedt and his associates attach most importance to the toxic substances produced by the action of *B. coli* and *B. welchii* on the intestinal juices above the obstruction, while others are of opinion that the enclosed secretions of the intestine or pancreas are the real toxic agents. The nearer to the duodenum the complete obstruction is produced, the more quickly does the animal die. Saito, Sakai, and Suzuki have made important contributions to this subject. They have shown that the onset of signs of toxæmia, after complete section of the duodenum, can be

greatly retarded or even prevented by establishing a flow of fluid in the small intestine below the obstruction. The introduction of saline or the transplantation of the uricr into the portion of intestine below the obstruction results in remarkable prolongation of life in experimental dogs. The application of these results to the question of chronic intestinal toxæmia seems to me to be justifiable. The indications are that the intact intestinal mucosa is a sound barrier to the entry of poisonous substances produced by the action of bacteria on foodstuffs or on the intestinal juices, and that the results of even complete obstruction in the lower levels of the intestinal tract, in so far as they are due to bacterial poisons, are extremely slow to appear. The signs and symptoms of toxæmia in these experiments are apparently as much the result of the mechanical disturbances of the tract below the obstruction as they are of the bacterial disintegration of the contents above the obstruction. Chemical studies have shown that many extremely toxic substances are formed by bacterial action in the intestine, but the absorption of these through the intact mucosa is a different matter.

In chronic ulceration of the tract from a variety of causes there is presumably an opportunity for toxic products to be absorbed, yet there is frequently no evidence of intestinal toxæmia in many of these cases. According to d'Herelle, mucus is the most important defence against invasion of organisms, and the activities of the mucous cells of the intestinal tract is all important in maintaining the health of the intestinal wall. Bond has expressed the view, based on experimental observations, that the mucus plays a biochemical, as well as a mechanical, part in the protection of mucous membranes against infection. Cramer, in experiments on rats fed on diets deficient in vitamin A, found that the mucosa of the intestine showed atrophy of the villi, and exhibited a peculiar condition of the mucous cells. As a result of this change bacteria had penetrated between the villi, and were found deep in the crypts of Lieberkühn and even within the mucous cells. Mottram has shown that similar changes occur as a result of radiation experiments and that the first change is an increase in the mucous cells, and subsequent atrophy and a profound change in the secretion of mucus. The occurrence of numerous bacterial infections in animals on diets deficient in vitamin A has been noted by many workers, and Cramer is of opinion that this is the result of the change in the mucous cells, which permits of the entry of organisms normally held at bay by the healthy secretion of mucus. Cramer, Mottram, and Kingsbury have shown, in support of this hypothesis, that organisms of relatively avirulent type may be obtained from the heart blood of such animals. In the radiation experiments coliform organisms were obtained in the blood by blood culture, and agglutinins to *B. coli* were found in the blood of the vitamin-deficient rats. Dietary deficiencies may therefore play an important part in determining susceptibility to infection from the intestinal canal.

This is a relatively new field of investigation and requires the participation of experienced bacteriologists. Webster and Pritchett have explored a part of this field in a series of experiments on mice. Mice of the same race and stock were fed on two diets differing in their vitamin content. One diet was the ordinary laboratory diet which had been in use for years, and on which previous generations of mice had grown and bred and appeared to be in good health, the other was a diet prescribed by McCollum, and was rich in vitamins. The two sets of animals were tested with a culture of *B. aertrycke* administered with the stomach tube. The mortality rate in the animals on the ordinary diet was extremely high, whereas that of the others was very low. Similar experiments were tried with *botulinus* toxin and mercuric chloride. The animals on the McCollum diet were much more resistant than the animals on ordinary diet. These workers remark that "possibly the future may reveal the existence of a deficiency operating insidiously and over a long period of time through many generations of animals."

It has already been noted that the hydrogen-ion concentration of the intestinal contents is an important factor in the flora. It has been shown that in rickets and in animals fed on a rickets-producing diet the contents of the

cæcum are alkaline (pH 7.4 to 8.0), and that the feeding of cod liver oil results in a change to the acid reaction comparable to that of rats on a normal diet (pH 6.2), which is not relieved by feeding oils deficient in vitamins. "The diets used to produce rickets all have an appreciable excess of base over acid, and rickets is not produced when such diets are made more acid" (Zucker and Matzner). The rickets-enrning effect of light is also associated with a change in the caecal flora to normal values. It is of interest to note that disturbance in the intestinal tract has long been held as a primary factor in the causation of rickets. Bacteriological studies of vitamin deficient animals might give much interesting information bearing on the normal intestinal flora and its relationships to changes in reaction of the caecal contents. That other processes may be involved in the intestinal tract when there is a deficiency of vitamin B has been demonstrated by Fridericia and others, who, in their studies of an extremely interesting condition called "refection," have shown that under certain conditions rats on a diet totally deficient in vitamin B may grow normally and show no signs of vitamin deficiency as a result of a change in the intestinal contents, this is supposed to be due to the development of a virus which is communicable to other animals through the faeces of the "refected" rats. They suggest that vitamin B may be produced in the intestine by some micro-organism in the intestinal tract. They have also noted that the bacterial flora of the cæcum of the "refected" rats is different from that of other rats. As in the other vitamin experiments the caecal contents of vitamin-deficient rats are markedly alkaline, whereas those of the "refected" rats are acid like those of normal rats.

There is probably no disease the cause of which has been so frequently associated with bacteria in the gastrointestinal tract as pernicious anaemia. Since the time when Hunter emphasized the occurrence of glossitis in cases of this disease an enormous amount of work has been done in an attempt to find in the mouth, stomach, or intestine the causative organism. Organisms with the power to haemolyse blood have in particular been sought. Within recent years it has been shown that in pernicious anaemia *B. coli*, enterococcus (*Streptococcus faecalis*), and *B. welchii* are present in abnormally large numbers in the stool, and that the flora characteristic of the cæcum encroaches on the higher levels of the intestine. In 1906 Herter showed that *B. welchii* or its spores were present in increased numbers in the stools of pernicious anaemia patients, and suggested that the products of these organisms, which are actively haemolytic, were absorbed from the intestine, and might be the cause of the disease. At a later period, when this organism had been shown to secrete an exotoxin, Herter's findings were confirmed, and experimental work in the production of anaemia with the *B. welchii* and its products gave some support to the idea that this organism was intimately related to the causation of pernicious anaemia. *B. welchii* is, however, present practically always in normal faeces, and in the comparison of strains from healthy persons with those from pernicious anaemia patients no differences in pathogenicity or in haemolytic power could be found. It was suggested that the increased numbers and the higher intestinal levels at which the organism could be found were probably the important features in its causal relationship. The absorption of toxin of *B. welchii* from the intestine was, however, extremely unlikely, as bacterial toxins of similar character, such as those of diphtheria and tetanus, may be administered in enormous amounts by the mouth without causing specific symptoms. Further, the absorption unchanged of such a toxin as that of *B. welchii* into the tissues would, according to all experience in immunity, lead to the production of antitoxin and a pronounced degree of resistance. It has also been found that no beneficial effects result from the administration of potent Welch antitoxin in cases of pernicious anaemia, and that *B. welchii* is present in equally large numbers in the faeces of individuals not suffering from pernicious anaemia, but in whom achlorhydria is present. In the absence of hydrochloric acid in the stomach an increased alkalinity of the duodenal contents results, with the appearance in the small intestine of a bacteriological flora suggestive of that in the colon.

The study of pernicious anaemia is a good illustration of the way in which abnormal conditions of the digestive functions may cause disturbance in the bacteriological relationships of the intestinal contents, disturbances which are too frequently reported as having an etiological relationship to the condition under investigation. The theory of intestinal toxæmia is still widely held among practitioners, and has been favoured by distinguished members of the profession. The absence of comparatively simple methods for examining the organisms in faeces, and the inadequacy of our information of the effects of changes in diet or the influence of particular foodstuffs, make it extremely difficult to define the "normal" flora. Ignorance of the variations which are found in normal persons is unfortunately reflected in the numerous contributions which appear in connection with the examination of the intestinal contents in a variety of diseases, and associated with cure or relief by the administration of vaccines made from a pathological intestinal flora. It is not generally recognized that many varieties of common intestinal organisms can be isolated from the stools of healthy persons, particularly if slight adjustments of the culture media are made or if special media are used. The ordinary media employed in the laboratory for the demonstration of pathogenic intestinal organisms are of use in the isolation of certain strains of coliform organisms only. The flora of the faeces even with regard to coliform organisms becomes considerably widened by the use of fluid media with different degrees of hydrogen ion concentration, or by the addition of substances which are inhibitory to certain common types. Browning has shown that the addition of brilliant green to peptone water results in the suppression of typical *E. coli* and the growth of mesitic fermenting strains, and that this method will demonstrate the presence of Morgan's No. 1 bacillus in samples of faeces which by direct plating on ordinary media do not yield that organism. Similarly a mixed growth of faecal organisms will show changes in types as a result of development of acidity in fluid media containing fermentable carbohydrates. We have found that a synthetic medium containing sodium citrate as the source of carbon and ammonium phosphate as the source of nitrogen (Koser's medium) gives a great many varieties of coliform organisms in the stools of normal persons. The demonstration of any of these strains in a sample of stool from cases of certain chronic maladies would we believe, immediately suggest to certain bacteriologists an "abnormal flora," and call for the exhibition of a vaccine. A recent paper on the use of residual vaccines in a wide variety of conditions may be quoted as representative of many others which have been published, advocating the use of autogenous vaccines of intestinal organisms. The author regards the occurrence of *B. lactis aerogenes*, Friedländer's bacillus, and Morgan's bacillus in the stool as of pathogenic significance, and such common coliform organisms as *B. acidi lactici* and *B. coli communis* are looked upon with suspicion. Whatever may be the therapeutic results obtained with vaccines, it is not justifiable to associate these common inhabitants of the intestinal tract as standing in causal relationship to the patient's pathological condition.

An increase in the numbers of streptococci in the stool, frequently judged only by a film of the faeces, is also used as an argument for vaccine treatment. A carbohydrate diet alone or the use of a simple saline purge may determine a marked increase of these organisms in the stool. From the standpoint of immunity, vaccine treatment cannot be expected to stimulate the production of antibodies which will be efficient against chemical substances produced in the intestine by the action of bacteria, and are only likely to be of value in cases in which the organism has penetrated the tissues of the body, some degree of entry through the mucosa must be postulated before the humoral defences of the body can operate. Only those who have a very restricted view of the flora of the intestinal contents and a very limited knowledge of the wide variations which occur in health, can with confidence recognize an "abnormal flora" and prescribe accordingly. In the adult stool many varieties of coliform organisms can be found, and the demonstration of these affords an explanation of the presence of the many "unusual types" which

are frequently encountered in cases of severe diarrhoea, dysentery, or other disturbed conditions of the intestine. These "unusual" strains are probably always present, but require special methods for their detection. It has frequently been observed that strains of *B. coli* isolated from the urine in cases of pyelitis are not the same as the prevailing types in the stool, yet their presence in the kidney has always been regarded as secondary to their presence in the intestine at some time or another.

The organisms which have been described as occurring in the stool form an extensive list and include many different groups of bacteria. Many of these are ingested in the food and dust, and are passively carried by the intestinal contents. Others find in the conditions at the different levels a suitable environment in which to multiply, and at other levels find the conditions inimical to their development. Before accepting an organism found in the stool as the causative agent, even in acute intestinal disorders, much evidence, other than its presence in considerable numbers or that it shows pathogenic properties on injection into experimental animals, must be presented. The spores of tetanus bacilli are frequently present in the faeces of man and animals, but it is almost impossible to determine whether the organism is passively carried by the contents of the intestine, as seems most likely, or is actively growing. The variety of organisms in the faeces and the chemical processes which occur in the intestinal contents suggest in many ways the organisms present in agricultural soils and the changes which they produce. In both situations similar groups of organisms are found, and the flora is determined by the nature of the available food material, and by the opportunities which are afforded for infection by many types of organisms, the difference in temperature of the two environments being the important factor in determining the prevailing type in the two situations. If the intestinal contents could more frequently be regarded as material which is outside of the tissues, and separated from these by a mucous membrane which is endowed with peculiarly selective absorptive power, there would be less tendency to regard the bacterial flora of the intestine or its individual members as concerned in the causation of many chronic conditions in the human subject.

KALA-AZAR AND ORIENTAL SORE THE PROBLEM OF TRANSMISSION *

BY

C. M. WELTON, CMG, CBE, MB, FRS,
Director in Chief, Wellcome Bureau of Scientific Research, London

The present-day position regarding the method of transmission of kala-azar, and of the parasitologically allied disease oriental sore, centres around sand-flies of the genus *Phlebotomus*, those minute irritating flies which transmit the febrile condition known as phlebotomus fever, which have long been suspected as being transmitters of oriental sore, and which have comparatively recently fallen under suspicion in relation to kala-azar. It may be said at the outset that though there is very good circumstantial evidence that these flies are the actual vectors of kala-azar and oriental sore, the final proof of experimental transmission has not yet been obtained, though there is every reason to suppose that when an infected sand fly bites an experimental animal or man himself the parasites are injected into the wound from the proboscis of the fly. The reason for this failure is not apparent, but it may be that unless the vertebrate host used for the experiment is in a particularly susceptible condition the small dose of organisms injected is insufficient to give rise to infection. It can hardly be that the organisms are not virulent, for if a sand fly which has infected itself by feeding on a case of the disease is dissected and the bulk of the organisms it contains is injected with a syringe into a suitable animal in the case of kala-azar or into man in the case of oriental sore, infection readily occurs. Though at the commencement of the sand fly work there appeared to be

* Read in opening a discussion in the Section of Tropical Medicine of the Annual Meeting of the British Medical Association, Cardiff, 1928.

every promise that the problem of transmission of the two diseases, kala azar and oriental sore, would be quickly solved, an unforeseen obstacle has arisen in that experimental animals and man fail to contract the disease even when fed upon by large numbers of heavily infected sand flies. Whether this obstacle will be overcome or whether it is an indication that, as has happened before in connection with these diseases, we are on the wrong track future work alone can disclose.

As the problem is still unsolved it will be advisable for us to consider other possibilities. In order to do this it is necessary to have some knowledge of the nature of the parasite which is known by the name "Leishmania," or, popularly, the Leishman-Donovan body. When it was first discovered, in 1903, by the late Sir William Leishman, and again in the same year by Donovan, its exact nature was not fully realized, but Sir Leonard Rogers soon showed by the culture method that it was a flagellate of the herpetomonas or, as I prefer to call it, the leptomonas type. Flagellates of this kind are essentially flagellates of insects and other invertebrates, in which they occur both as the non-flagellated body, like the Leishman-Donovan body, and as the elongate flagellated leptomonas, which, in the case of the human parasite, is hardly, if ever, found in the human body, but which occurs in cultures and in the intestine of certain insects, particularly the sand fly and bed bug which have ingested the small round forms. In all cases in which the life cycle of an insect leptomonas is known it has been found that infection is spread from insect to insect by means of small round forms, which have the structure of the Leishman-Donovan body and which escape in the faeces of the insect. The common leptomonas of the flea, *Leptomonas stenoccephali*, is a flagellate of this type, and it is spread from flea to flea by such forms which escape in the faeces and are ingested by the flea larvae. In the insect itself the infection in all cases tends to be one of the hind gut. So essentially are the leptomonas flagellates parasites of insects and other invertebrates, that it is safe to assume that the parasites of kala-azar and oriental sore were originally insect flagellates, like that of the flea, which passed from insect to insect, and that the infection of human beings came at a later period.

It has been suggested that the parasite of kala azar might pass directly from man to man, and in support of this might be brought forward the observation of Perra, who showed that in kala azar the villi of the intestine may be packed with macrophages filled with parasites in such a manner that escape into the faeces would seem to be inevitable. Furthermore, it has been shown by Shortt that parasites do actually occur in the urine, so that contamination of water is a possibility. There are isolated observations which indicate that man-to-man infection is a possibility. Thus, Archibald in 1914, in the Sudan, infected monkeys by feeding them with infected spleen material while Adelheim, in 1924, reported that a healthy mouse kept in a jar for five months with an infected mouse contracted the disease. There is no evidence, however, that the Leishman-Donovan body can survive in water. It certainly cannot assume the flagellate stage in this medium, and, unless we are to ignore entirely the fact that the parasite can develop into a flagellate we must give up the idea of man-to-man infection as the normal method of spread of the disease.

So important to my mind is the flagellate stage which occurs in cultures and in the intestine of insects, and so characteristic is it of an insect flagellate, that there appear to be overwhelming reasons for believing that the Leishman-Donovan body must have an invertebrate host. Not the mere fact that the Leishman-Donovan body can develop into a flagellate in the stomach of an insect is not in itself proof that such an insect is the host. As first shown by Patton as long ago as 1907 in India, bed bugs fed on kala azar cases will ingest parasites which, during the next few days in the stomach of the bug, develop into the flagellate stage. There is, however, no great multiplication in the bug. If few parasites are ingested, few flagellates appear, and vice versa. If the bug had been the true invertebrate host we would have expected that if only a few parasites had been ingested, eventually many flagellates would have

developed. Furthermore, the flagellates tend to die out in the bugs, a second feed of blood being particularly fatal to them. In true insect hosts of any flagellate the organisms increase in number progressively and tend to persist for the remainder of the insect's life. Another point of some importance is that in the case of flagellates in the real insect host these show a tendency to attach themselves to the intestinal epithelial cells by their flagellated ends, the whole epithelium being sometimes covered with them. No such attachment occurs in bugs, so that, quite apart from the lack of correlation between the distribution of bed bugs and kala azar, there is good reason for believing that the bug is not the vector and that the development into flagellates which occurs in the bug's stomach is a pseudo-development and occurs merely because the stomach of the bug contains a quantity of blood. The development is comparable with that which occurs in blood media in the test tube. I myself in 1911 showed that the parasite of oriental sore would similarly develop in the bed bug but no one would suppose that the bed-bug is the vector of this disease. As a matter of fact, trypanosomes, spirochaetes, and other organisms will multiply to some extent and survive for relatively long periods in the stomach of this insect. There is no question of the bug being a vector of these various organisms. I think, therefore, we are justified in ruling out the bed bug, even though Young has recently stated somewhat casually that he and Hertig were successful on one occasion in effecting transmission of kala azar from one hamster to another by its means. Nicolle and Anderson in 1925 announced the complete failure of a laborious attempt to transmit the disease from dog to dog by the bed-bug.

In the Mediterranean region, where kala-azar occurs chiefly in the infantile form, not infrequently dogs, and very rarely cats, suffer from the same disease. Basile and other Italian workers very naturally thought that the flea might be a vector, and this idea was strengthened when it was found that fleas taken from infected dogs harboured flagellates similar to the Leishman-Donovan body and the flagellates which develop from it. It was not at first realized that fleas, as I have already mentioned, are liable to a leptomonas infection which is peculiar to themselves. It was subsequently shown that the Leishman-Donovan body would not develop in fleas and very careful experiments by myself, Pereira da Silva, and Nicolle and Anderson have failed to effect transmission of the disease from dog to dog by these insects. The flea hypothesis, like that of the bed bug, has therefore been abandoned, so far as I am aware, by all observers. Numerous other blood-sucking arthropods have been tested, with results even less encouraging than those obtained with bugs and fleas. Even the ancylostomes, which attach themselves to the mucosa of the intestine and suck blood, and thus are very probable ingesters of Leishman-Donovan bodies, have been carefully examined for flagellates or other stages of the parasites, with negative results.

The whole position of the problem of transmission of kala-azar and oriental sore reached a stage when it appeared to be more obscure than ever. Then the interesting discovery that the parasite of kala-azar would develop in the Indian sand fly *Phlebotomus argentipes* was announced by Knowles, Napier, and Smith working in Calcutta in 1924. It was also observed by Sintou that there was a relationship between the distribution of this sand fly and kala-azar in India. The observations were quickly confirmed by Christophers, Shortt, and Barrard with the same sand-fly in Assam, and by Young and Hertig, and Patton and Hindle in North China with sand-flies of that locality. Furthermore Adler and Theodor in Palestine, and Parrot and Donatien in Algeria, showed that the parasite of oriental sore would similarly develop in sand flies. The important point about this development was that it was a progressive one, and, unlike the development which had been demonstrated to occur in the bed-bug, a relatively small number of organisms ingested by the fly led to a massive infection of the stomach. Furthermore, the flagellates showed a tendency to attach themselves to the cells, so that in both these respects the organism was behaving in the sand fly as a flagellate would be expected

to do in its true invertebrate host. In one direction, however, there is a marked difference from all known insect leptomeres. As noted above, the infection in the insect tends to be one of the hind gut, from which small rounded bodies, resembling the Leishman-Danovan body, are voided in the faeces. In the sand-fly infected by feeding on a case of kala-azar or oriental sore, no such infection of the hind gut occurs. On the contrary, the development of the flagellates occurs in the stomach, particularly in its anterior part, and there they show a tendency to attach themselves to cells. Having produced a massive infection of the stomach, the flagellates may extend forwards to the oesophagus and thence into the buccal cavity. Furthermore, there is no tendency towards the production of the small round Leishman-Danovan bodies, which are so characteristically formed in the hind-gut in the case of insect flagellates. Adler has shown that if an infected sand-fly feeds through a rabbit-skin membrane on a sterile fluid, flagellates can afterwards be demonstrated in the fluid, an observation which proves conclusively that the organisms escape from the proboscis when the sand-fly feeds. The development of the flagellates in the anterior part of the alimentary tract is thus not associated with any development in the hind gut, nor with the passage of small rounded forms in the faeces, though occasionally isolated flagellates occur in the hind-gut, doubtless as a result of having been swept there from the heavily infected stomach. It seems very probable that the parasites of kala-azar and oriental sore originally lived in some insect and gave rise to an infection of the insect type—namely, infection of the hind-gut and passage of rounded forms in the faeces. If this original insect host was the sand-fly, we must assume that the infection in the fly has altered in character from one in the hind-gut to one in the anterior part of the alimentary canal. However, there appears to me to be another possibility. The sand fly may not be the original host. The flagellate, as the Leishman-Danovan body, having become established in man, it is evident that any blood-sucking insect would be able to ingest parasites by feeding on the human being, as the parasites occur both in the circulating blood and in the skin. If the conditions in the insect were favourable to the development and multiplication of the flagellate it would come about that such an insect would become infected with flagellates.

It may be that the sand-fly is an insect of this type, and that the development which occurs in the anterior part of its alimentary canal is to be explained on the assumption that it has become secondarily infected from human beings, who in the first place acquired the parasites from some insect in which the flagellates lived, as do other insect leptomeres. This does not mean that the sand-fly would be unable to transmit the infection, but it would indicate that if the original hypothetical insect host still exists the virus would be able to maintain itself by direct passage from insect to insect without necessarily infecting man.

It seems to me simpler to regard the sand-fly as a secondary insect host than to admit that an original hind-gut infection has in the same fly changed to one in the anterior part of the alimentary canal. The same difficulty occurs in the case of trypanosomes transmitted by tsetse flies, where an anterior development also occurs, and it is possible that a similar explanation will hold in their case also. If the original insect host still survives, the problem of the eradication of the leishmaniasis would be a difficult one, for there would then be a permanent insect reservoir of the virus.

The remarks which I have just made show that sand-flies can readily be infected by allowing them to feed on cases of kala-azar or oriental sore. In cases of oriental sore where the lesion is in the pre-ulcerative stage a sand-fly feeding on it readily takes up leishmania, as these parasites occur in myriads enclosed in large macrophages or clasmotocytes just below the epidermis. In the case of kala-azar, the presence of parasites in blood films made from the peripheral blood has been demonstrated, and it has generally been supposed that the sand-flies ingest the parasites in the circulating blood. Observations by Cash and Hu have shown, however, that in experimentally infected hamsters, and even in human beings suffering

from this disease, the skin may contain larger numbers of macrophages packed with parasites. They have suggested with good reason that it may be that sand flies infect themselves from the parasites in the skin, and that in many cases when parasites have been found in films of the peripheral blood these may actually have been derived, in some cases at least, from the skin. Hindle has made some observations which indicate that a relationship exists between intensity of the skin infections in hamsters and the percentage of flies which become infected after feeding on them. Cases of Indian kala-azar may show a peculiar skin eruption, first described by Bramachari in 1922 as dermal leishmanoid. In this condition, which is by no means uncommon, there occur cutaneous nodules harbouring parasites. It would be a relatively easy matter for sand-flies to take up parasites from these lesions as they do in oriental sore.

Not only do flies become infected by feeding on human beings, but also when fed on experimentally infected hamsters, and in mentioning these little rodents I must emphasize the great importance of the discovery of Smyly and Young in 1924, in China, that the hamster is very susceptible to inoculation with the parasite of kala-azar. Before this observation the lack of a susceptible laboratory animal was a serious handicap to kala-azar research. Now the virus can be maintained with ease in the laboratory, and it is a simple matter to feed sand flies or other insects on the hamsters. It is of interest to note that Young and Hertig reported in 1925 that they had examined 4,480 wild hamsters for the occurrence of natural infection. Out of this number one was found to have a heavy infection. It had come from a locality where 5 per cent of the inhabitants suffer from the disease. It would not appear, however, that the hamster can in any way be regarded as a reservoir of the virus. In experiments the hamster is much more susceptible to intraperitoneal injections of the virus than to cutaneous ones, and this may explain why workers in India and China have failed entirely to infect hamsters by allowing hundreds of infected sand flies to feed on them, while the flagellates taken from infected sand-flies and injected intraperitoneally readily produce infection. It is evident that the dose of flagellates injected into the skin by a large number of sand flies is, as far as present records show, insufficient to produce infection. It seems that recourse must be had to human experiments, and I understand that these are being carried out with volunteers in India—an experiment which is attended with little danger now that a practically certain cure is available in the various organic antimony compounds when employed in the early stages of the disease. Even these experiments may not at once give results, for the factor of susceptibility of the individual is an important one. Thus Maggione in 1925 failed to infect human beings by intracutaneous and subcutaneous injection of virus taken directly from cases of kala-azar.

Assuming that sand flies of the genus *Phlebotomus* are the actual vectors of kala-azar and oriental sore, how can the parasites in the flies be transferred to human beings? From what I have said of their presence in the anterior part of the alimentary tract, and the fact that they escape from the proboscis into a fluid on which an infected sand fly is feeding, it is legitimate to conclude that they actually enter the wound inflicted by the sand-fly during the feeding act. There are, however, other possibilities. In common with many other blood-sucking insects the sand fly ejects fluid from the rectum while it is feeding. In the case of the transmission of *Trypanosoma lewisi* from the flea to the rat it is in such ejected droplets that the infective forms of the trypanosome occur. The droplets are licked from the fur by the rat, which thereby becomes infected.

As already noted, occasional flagellates may be found in the hind gut of the sand fly as a result of having been washed there accidentally from the stomach, and this being the case it is probable that on very rare occasions flagellates would escape in the droplets ejected from the rectum. The number, however, would be very small, and in any case would hardly be greater than the number injected by the sand-fly from its proboscis. The ejected droplets fall on to the skin while the sand fly feeds, and the subsequent

scratching as a result of the irritation, might lead to infection of the skin or conveyance of material on the fingers to the mouth or conjunctiva. The dose of organisms would be so small that it hardly seems probable that infection would occur in this way when that injected directly into the skin from the proboscis fails to infect. There is, however, another consideration. The heavily infected sand-fly might be intentionally or inadvertently crushed on the skin, with the result that a very much larger dose of organisms would be deposited. In the case of the transmission of relapsing fever by the louse, it is the fluid from the injured or crushed louse which brings about infection by contamination of the skin or conjunctiva. It has been shown by Adler and Theodor that if a sand fly infected with the parasite of oriental sore is dissected and the bulk of the organisms it contains is injected into the skin of a human being, infection results, so that in the case of this disease the crushing of an infected sand fly on the skin might easily give rise to infection. In the case of kala azar, however, there is no evidence that the injection into the skin of organisms from an infected sand-fly will produce infection, though it would probably do so in some cases, as hamsters may occasionally be infected by the subcutaneous injection of the flagellates from the culture tube. Hindle and Patton have actually attempted without success to infect hamsters by inoculating flagellates from sand-flies into the skin by rubbing them into excoriations of the skin, and by introducing them into the mouth. It is possible, however, that under certain favourable conditions the scratching into the skin of a large dose of organisms from a crushed sand-fly or the conveyance on the fingers of such a dose to the mouth or conjunctiva might produce infection. If experiments designed to transmit infection by the bites of infected sand flies continue to fail, as they have done up to the present then it appears to me that the other possibilities I have just mentioned will have to be still further investigated.

As regards the particular sand flies involved in India, it is *Phlebotomus argentipes* which, as already stated, corresponds fairly well in its distribution with that of kala-azar. Another sand fly, *Phlebotomus papatasi* has also been infected in Calcutta but with greater difficulty. Thus of 102 *P. argentipes* fed on kala-azar cases by Napier in Calcutta 43 showed subsequent infections, while of 101 *P. papatasi* only 2 became infected. Shortt, Barraud, and Craighead on one occasion found a naturally infected *P. argentipes* which had been caught in a kala-azar house in Bihar. It is not probable that *P. papatasi* has any significant share in the transmission of the disease. In North China *P. argentipes* does not occur, and in fact there is no knowledge of any sand flies south of the Yangtze a distribution which is again in accord with that of kala-azar in this endemic area. Young and Hertig showed that both *P. major* var. *chinensis* and *P. sergenti* var. could be infected by feeding on infected hamsters, the former in their hands more readily than the latter. Patton and Hindle found that both these flies could be readily infected and in addition infected them by allowing them to feed on human beings suffering from the disease. In the case of *P. major* var. *chinensis* the development of flagellates in the stomach is marked, many of the organisms attaching themselves to the lining epithelium. In many flies they extend forward along the oesophagus to the buccal cavity and down the proboscis. The infection persists in the flies after the blood has been completely digested and disappeared. In the case of *P. sergenti* var., however, though development occurs in the stomach there is no extension forwards, while the infection disappears with the digestion of the blood. It is therefore less likely to be a vector than *P. major* var. *chinensis*. It is thus apparent that as in India *P. argentipes* is a more efficient host than *P. papatasi*, so in North China *P. major* var. *chinensis* is more efficient than *P. sergenti* var.

There is as yet no information available regarding the relationship of kala-azar to sand flies in other endemic centres of the disease, such as the Mediterranean region, Transcaspia, the Sudan and Kenya, the districts around Lake Chad, and South America. It will be sufficient to state that Adler and Theodor, working in Palestine, have

succeeded in producing infections in *P. papatasi* by feeding them on cultures of various strains of leishmania, but I do not think the results so far obtained throw much light on the problem of transmission in the localities I have just mentioned.

Turning now to oriental sore, the sand fly has long been considered to be a possible vector. In 1912 I described a leptomonas which occurred in sand-flies in Aleppo. This flagellate was not rediscovered till Adler and Theodor found it in 1925 in *P. papatasi* in Jericho, unless the claim of Laveran and Franchini, about which there appears to be some doubt, that they found it in these sand-flies in Italy in 1920, is substantiated. Flagellates from naturally infected sand flies were inoculated by Adler and Theodor into the skin of human beings. Oriental sore developed, and from these lesions other laboratory-bred sand flies were infected. The flagellates in these flies were again injected into the skin of a volunteer, who contracted the disease. Previous to this Seigent, Parrot, Douatiou, and Begnet in 1921 inoculated into the skin of a human being the crushed up bodies of seven *P. papatasi* which had been sent to Algiers from Biskia, an endemic centre of oriental sore. Though no flagellates were seen in the material inoculated, a typical oriental sore containing leishmania developed. Parrot and Douatiou in 1926 found naturally infected sand flies of this species in Biskia, and succeeded in infecting sand flies by feeding them on the tail lesions in infected mice. The evidence connecting *P. papatasi* with oriental sore is parallel to that associating *P. argentipes* with kala-azar in India and *P. major* var. *chinensis* with this disease in North China, with the exception that naturally infected sand flies have not yet been found in the last-named area. Adler informs me that during a visit to Baghdad he has found there, amongst other sand flies, *P. sergenti*, and that it is also a possible vector of oriental sore as he has succeeded in infecting it. The only evidence of the method of transmission of cutaneous leishmaniasis in South America where the disease is very prevalent, is afforded by an experiment described by Aragão in 1922. This observer fed some specimens of *P. intermedius* on a human lesion and later inoculated the crushed up sand flies into the skin on the nose of a dog, which developed a characteristic sore.

Time will not permit of a discussion of the leishmania and leptomonas infections of vertebrates other than man. As already noted, dogs in the Mediterranean area are liable to suffer from kala-azar, while in various endemic centres of oriental sore these animals not infrequently contract the disease. There is no reason to suppose that the organisms infecting dogs are different from those which produce the diseases in man. Lizards, such as the gecko and chameleon, may be infected with flagellates of the leptomonas type, and at one time in North Africa it was thought that the gecko, on which sand-flies readily feed, might be a reservoir of the virus of oriental sore. Experiments did not support this view, though the recent statement of Young and Hertig that the flagellate from the gecko will infect hamsters and produce lesions similar to those caused in these animals by the virus of Mediterranean kala-azar opens up another possibility—namely, the identity of the gecko flagellate with the parasite of North African kala-azar. Some observers have tried to connect with oriental sore the naturally occurring leptomonas infections of euphorbias and other plants. Strong has even suggested that in Central America, where these plant infections occur, the plant bugs acquire an infection by feeding on the plants, and a certain lizard an intestinal infection by devouring the bugs. Flagellates from the lizard inoculated into the skin of a monkey produced a lesion in which leishmania-like parasites occurred. These and many other aspects of leptomonas infections open up fields of inquiry which still await exploration.

In conclusion, it may be stated that if the sand fly is not the transmitter of the leishmania infections of man we are as far off the solution of the problem as we ever were. The remarkably intense infection produced in this insect is difficult to regard as an accident, and the mass of experimental evidence is in favour of the view that both kala-azar and oriental sore are transmitted by species of

Phlebotomus On account of the failure of experimental animals, on which infected sand-flies have been allowed to feed, to develop the disease, Young and Heity, have begun to doubt if the sand-fly is really the vector of kala-azar in North China. Woakes should not, however, be discouraged by such a temporary set-back, and until every channel has been thoroughly explored it would be foolish, in face of all the evidence, to abandon the theory of sand-fly transmission of this disease.

CHRONIC ETHMOIDITIS *

BY

ROSS HALL SKILLERN, M.D.,
Philadelphia

WHEN a foreigner offers a treatise before a gathering of this sort which is really international in its scope, it is more or less understood and expected that his presentation will be rather in the form of a compilation taken from every available authority, and will in the end leave the listener to draw his own conclusions as to the relative efficacy of the various methods described. Now I propose to deviate from this custom and present the subject entirely from our own point of view—in other words, give it as we see and understand it, with the treatment that we have found most suitable for that particular case or condition.

Chronic infections of the ethmoid, as is now well understood, can broadly be divided into the suppurative and non-suppurative. In the first instance an infection is present characterized by the formation and exudation of a purulent secretion, accompanied by the appearance in the ethmoid region of a more or less widespread catarrhal inflammation. The purulent secretion varies in its consistency, at one time being thin, acid, and almost watery, and at another time assuming the characteristics of a thick yellow discharge, the same as that which the older surgeons were wont to term *laudable pus*. In the ordinary case variations between these extremes were the rule rather than the exception, depending upon, as the patient would say, the acquisition of a fresh cold, which usually was not the case, but in reality, represented rather an acute exacerbation of his chronic condition. This would naturally account for the changes in the consistency of the secretion, sometimes thick and profuse, sometimes thin and scanty, and often inducing an erroneous belief that a cure was in progress. As the infection spread, the discharge, particularly that collecting during the night, became more constant, resulting finally in that condition of a chronic purulent ethmoiditis which is so well known to us all as to obviate the necessity of further description.

The other form of ethmoiditis—the non-suppurative type—is a much later development, although it was recognized in a way by some of the early pioneers—as, for example, Woakes of this country and Bosworth of my own—but it was not until after Uffenord published his treatise that it obtained universal acceptance. The type I refer to is that form characterized by polypoid hypertrophies, and even true polyp formation, unaccompanied by true leucocytosis. Hitherto Zuckerkandl's postulate, that the polyps were the products of the purulent secretion, had been accepted without question. Even after the publications of the microscopic pathology, both in Germany and the United States, much doubt was expressed as to the proper interpretations of these findings, many months, I might add years, elapsed before this doctrine was accepted at even its face value. I think we all now recognize hyperplastic ethmoiditis as a separate and distinct pathological entity, in contradistinction to the earlier known suppurative infection. The fact that these two can and do occur as separate forms does not preclude the possibility of them being combined and occurring as hyperplastic infection with suppuration. As a matter of fact the probability of suppuration is directly related to the extent of the hyperplasia, the greater the polyposis the more likely is it that the commoner forms of saprophytic micro-organisms will

find a suitable site for their growth with the formation of their suppurative products. When suppuration once gains a foothold I have never seen it disappear.

Since the ethmoid labyrinth is not only divided into two portions (the anterior and posterior) by a complete partition, but these are also subdivided into numerous chambers (cells), and since these may be individually affected, it would be well before taking up the treatment to make a more comprehensive classification. Following this the indications for surgery, with special reference to certain methods, will be greatly clarified.

Suppurative

- (a) One or more of the anterior cells
- (b) One or more of the posterior cells
- (c) Combined, affecting both anterior and posterior cells

Hyperplastic

- (a) Localized hyperplasia (small polyps)
- (b) Anterior labyrinth
- (c) Posterior labyrinth
- (d) Intracellular
- (e) Extracellular
- (f) Combined
- (g) Suppurative infection

The three types (d), (e), and (f) may merely represent an extension of the inflammatory process and can occur equally in any part of the labyrinth. The last type represents the final stage, when either a new infection occurs or the old one has advanced so far, and the tissues have become so infiltrated, as to invite leucocytic diaporesis, with the formation of a purulent secretion.

Suppuration in One or More of the Anterior Cells—This intranasal type, so far as I am concerned, as an individual entity is non-existent, with one exception.

Of course, when an orbital ethmoid cell situated behind or external to the frontal sinus and outside the nose is present, it may easily become infected and simulate a frontal sinusitis, but as we are concerned only with that portion situated within the nasal cavities this lies beyond the scope of our presentation. The remaining anterior cells (with the exception noted above, which I will come to later) are those known as the infundibular, which includes the frontal bulla, when present, and that one lying within the angle of the nose. I do not recollect ever observing a circumscribed chronic purulent infection of the mucosa of these cells unaccompanied by infection of the frontal sinus. Presumably this is possible, but, as it has never come under my own observation nor that of my colleagues, its occurrence is, so far as I am concerned, only of academic interest.

The exception referred to is a purulent infection of the living membrane of the bulla ethmoidalis. Formerly abscess in the bulla was considered an event of no common occurrence, but this was probably due to the fact that when present it so overshadowed other infection as to cause the latter to be entirely overlooked. However, other things being equal, the evacuation of a badly diseased bulla will bring about a cure, despite the fact that the infection has embraced other cells in the immediate neighbourhood.

Purulent Infection of the Posterior Cells—That these cells are more frequently the seat of chronic disease is due to a number of conditions. In the first place, they are larger and more numerous, and, secondly, they are so situated as to be less amenable to aeration. Their drainage can easily be interfered with by slight swellings of the nasal mucosa, and, lastly, their anatomical situation prevents easy access to exact diagnostic instrumentation, even with the aid of the nasopharyngoscope. Being but slightly disturbed by the inspiratory air currents they offer a fine site for micro-organismal growth once infection has taken place. This extension may be so gradual and insidious that the patient is unaware of the seriousness of the condition until a well marked infection has occurred, he has, it is true, noted the unwanted post-nasal discharge and stuffiness in the nose, particularly on arising, but, as the inconvenience is not great, he attributes the whole matter to a particularly tenacious cold. This, however, is noted more in the hyperplastic variety than in the suppurative.

The combined form affecting both the anterior and the posterior cells, is always more open in its course, and it

* Read in opening a discussion in the Section of Laryngology and Otology at the Annual Meeting of the British Medical Association, July 1928.

usually represents (in contradistinction to the other types) the direct sequels of an acute infection, or perhaps a series of acute inflammatory disturbances. In the event of such a widespread infection the symptoms are so apparent as to obviate further elaboration.

The Hyperplastic Types.—These pathologic conditions appear when a portion of the ethmoidal mucosa undergoes hyperplastic changes, they may range from a condition of slight degeneration in a small portion of the lower border of the middle turbinate to the formation of actual sessile polyps the size of a small oyster. While the lower edge of the middle turbinate appears to be most frequently affected, nevertheless the actual polyps, when present, appear to take their origin higher, having their bases in the body of the ethmoid or along the uncinate process. I do not recall ever having observed large single polyps originating along the lower edge of the middle turbinate. The anterior labyrinth is usually the seat of the large extracellular hypertrophies which hang more or less loosely in the nasal cavities, while in the posterior labyrinth the intracellular variety, hidden from view, is the rule. This is probably due to the fact that there is more room for growth anteriorly beneath the turbinate than posteriorly between the body of the ethmoid and the nasal septum. The large so-called choanal polyps do not as a rule originate in the posterior cells, but if traced to their source will be found to spring from the mucosa of the maxillary sinus forcing their way out through the pars membranacea and extending into the nasopharynx through the medium of a long pedicle. Of course in either labyrinth the primary affection, whether it be intra- or extra-cellular, may become combined, this, after all, only represents in either case an extension of the pathological process from within outward, or without inward, as the case might be. This is well illustrated in those old chronic cases where the entire ethmoid, from the uncinate process to the anterior sphenoidal wall, is one mass of polypoid degeneration. All of us have seen such cases continuing for years accompanied by a profuse watery secretion which would dry on the handkerchief, causing a stiffness, but not staining the linen. When infection by the *Staphylococcus aureus* occurs the secretion becomes thick and yellow, with the characteristics of true pus, but this seems to appear in cycles, particularly on the acquisition of every fresh cold. The true combined form only becomes permanent when the micro-organisms find lodgement deep in the mucosa. Even then the suppuration appears to be different from that caused primarily by the influenza bacillus, for in the first instance the secretion seems to be more profuse and is easily discharged—the nasal passages are comparatively clear—while in the latter the pus is thicker, more tenacious, and exhibits a great tendency to form into crusts.

TREATMENT

The successful treatment of all sinus infection, particularly where the ethmoid is concerned, has for its basic principles aeration and drainage, with emphasis on the former. We have long since felt that the old dictum of removing all infected ethmoid tissue, irrespective of the kind and extent of the inflammatory process, was as unnecessary as it was radical, for more recent experience has shown us that with proper assistance nature will do much to bring about a resolution of the mucosa in diseased cells after proper aeration has been established. This tendency of nature is of no little importance when we call to mind some of our earlier ethmoid cases which were in the beginning perhaps mild, but after our well-meaning surgical intervention were transformed into a disorganized suppurating mass with landmarks obliterated and with augmented subjective discomforts instead of relief. Observing these results, not only in my own practice but in that of my colleagues, I was prompted to seek the solution, and found that over-enthusiasm was the cause of my undoing. Instead of sending a boy to do a man's work, I went to the other extreme and sent a man to do the work of a boy. In other words, I was prone to overdo the removal of ethmoid tissue rather than to conserve it, thinking that to leave even the slightest amount of diseased mucosa behind would result only in a nidus from which the infection would gradually spread until the condition became as bad or even

worse than before the operation. In those days drainage was our duty, the *sine qua non* of a successful treatment. Ventilation, it is true, was looked upon as a desirable but not necessarily an indispensable adjunct. A suppurating cell should not only be opened but completely eradicated, encroaching upon healthy neighbouring tissue if necessary, in order to bring about our purpose. Now, thanks to our experiences with the sphenoid, in which we saw hyperplastic tissue almost filling the cavity shrink down in a few days under our very eyes until in a short time it was again normal, all this has changed. We know now, and confidently expect, that nature, with a little assistance, will effect a far better and cleaner operation, and procure a physiologically functioning area of tissue in the ethmoidal region, while we, with our widespread and oftentimes haphazard procedures, only leave an area of debris, which soon becomes reinfected and degenerates into a disorganized fibrous suppurating mass.

It is to anticipate this very eventuality that I propose to lay before you for your consideration the various forms of treatment as practised by us at the present time. It is not in the form of a recommendation, but rather as a communication, that these are presented, not to be taken as dogmatic in any sense, but rather at their face value for what they may be worth.

Let us begin with the mildest of the suppurative type, and ascend until we have the severest complicated form to deal with, applying their appropriate treatment as each is met.

Simple catarrhal infection is characterized by mild headaches, stuffy nose, and a fairly constant thin mucoid discharge, becoming thick and yellow at times, the patient being apparently very susceptible to attacks of acute coryza. Rhinoscopic examination often shows little more than hyperaemia and congestion of the mucosa when compared with the opposite side. Pus is conspicuous by its absence, at least so far as the examiner is concerned. However, the patient often states that considerable discharge, particularly post-nasal, is in evidence during the morning hours. This form yields slowly to the old shrinking and cleansing treatment, but shows a great tendency to recur. To obviate this I have found the removal of the swollen and often infected middle turbinate almost a *sine qua non*. The purpose of this is, first, to permit thorough aeration and ventilation of the diseased cells, and, secondly, to furnish sufficient space to make possible the applications of cotton poultices, which are saturated with certain medications. In given cases, where the nasal passages are congenitally narrow and the mucosa of the septum greatly thickened, I have found it necessary to resect that part of the septum in its entirety, making a large perforation so that these membranes could no longer swell and compress that of the ethmoid on its respective side.

After the middle turbinate has been removed and the roughened edges smoothed, nothing further is done, even though the temptation be severe, the parts are allowed to heal. After five days have elapsed the treatment by means of the tampons is instituted. This consists of the application of a cotton tampon saturated with a 10 to 20 per cent solution in half water, half glycerin, of a non-irritating silver preparation, which covers the ethmoid from the anterior sphenoidal wall to the uncinate process. This should be allowed to remain *in situ* at least five hours. I use a preparation called *silvol*, but there are others which to all intents and purposes are identical. These applications deplete the tissues of their inflammatory content by the hygroscopic action of the glycerin, thereby permitting the silver to penetrate partially the cellular interstices and bring into action its germicidal and astringent effects. In order to obtain the maximum effect three things are essential: the solution should be freshly made, it should be warm, and the tampon should remain in place five or more hours. These treatments are instituted at first every other day gradually tapering off directly in accordance with the improvement noted. This usually requires only a few weeks, since the affection readily yields to this form of treatment.

Purulent infection confined to the anterior cells, as a disease *per se*, is one of the rarest we are called upon to treat. It is true that occasionally one sees an infected and

suppurating bulla ethmoiditis, and even an orbital ethmoidal cell which simulates a frontal infection, but when the anterior cells are suppurating we have an infected frontal sinus which is also secreting pus. In these circumstances a cure of the underlying ethmoid depends upon first ridding the frontal sinus of its infection. Sometimes after this is accomplished the bulla will continue to secrete owing to the ostium becoming partially occluded from the inflamed and swollen mucosa, thereby seriously interfering with the normal drainage and pinetically eliminating aeration. When this eventuality occurs it will be necessary to open the floor of the bulla and reinstall both drainage and aeration. If this is the sole remaining focus of infection a cure speedily follows.

Suppuration in one or more of the posterior cells, although not uncommon, is one of the most difficult of sinus infections to detect or to diagnose early. The reason for this is apparent when we consider the mild and oftentimes vague symptom-complex together with the almost inaccessible location, even to the nasopharyngoscope, of these posterior cavities. We can study with a fair degree of accuracy the cells emptying into the superior nasal passage, but those which lie to the outside of these and those lying in the depth of the sphenoidal fissure are beyond our inspection. Indeed, many of these cases, consisting of a low-grade infection in one or more of the cells, have escaped detection for years, having been considered to be merely a chronic catarrhal condition, until the sudden appearance of a severe ocular disturbance invited immediate attention, which then resulted in the discovery of a latent sinusitis. One clue, however, is always at hand if we are sufficiently astute to take advantage of it, and that is the appearance of the middle turbinate. The body of this structure appears slightly hypertrophied, and often has a mottled appearance. While to the casual observer this may escape notice, yet if one carefully compares the turbinate with its fellow on the opposite side, the difference will at once be apparent.

The logical treatment is, of course, to secure better aeration and drainage, which can only be accomplished by the total removal of the middle turbinate. This resection not only aids materially in contributing to these therapeutic advantages, but incidentally brings under our view those cells which subsequently may necessitate opening. Unless the suppurating areas have been disclosed accurately, or unless symptoms are pressing, it is well to wait for a few days in order to determine definitely the exact seat of the infection before attacking these cells. The silver poultices will be of great advantage in this determination. I have often seen an apparent general suppuration under this treatment localize itself into one or two defined regions, which lent themselves admirably to instrumental procedures. Formerly it was our practice to excavate completely all these posterior cells when infection was discovered in their midst, but now we open with the hook, and with the Grünwald forceps remove only the diseased portion until healthy tissue is reached. In this way we have not only procured quite as good end-results so far as a cure was concerned, but we have conserved tissue which certainly possesses a normal functioning activity. After these cells have been opened and exposed to thorough aeration, nature speedily effects a cure which is in direct relation to the thoroughness of the operation.

Combined suppuration affecting the entire labyrinth is usually an old one where the middle turbinate has long since been sacrificed, but from one cause or another the infection has gradually spread until both the anterior and posterior cells are more or less involved. Nothing but a so-called complete exenteration will be of the slightest permanent avail in these cases. In our experience the crux of this situation lies in the preliminary removal of the uncinate process, for by this step we gain from 1/8 to 3/16 inch of room, which may prove of inestimable value in reaching the agger and infundibular cells, to say nothing of the depths laterally to the sphenoidal recess. This can be readily accomplished with a flat chisel without particular danger in careful hands.

After the mucinate has been removed the posterior-living cells may be methodically attacked and resected, keeping close to the orbital plate until the anterior sphenoidal

wall is reached. It is well to leave a certain amount of the inner wall of the ethmoid *in situ*, particularly that portion which houses the terminal filaments of the olfactory nerves. While it has been shown that infection may travel through the cut sheaths of these nerves and enter the meninges, nevertheless I do not fear this so much as I desire to preserve the sense of smell in this locality. Regarding the occurrence of meningitis following the severance of these nerves, it must be a very infrequent occurrence, otherwise all of us would one time or another have met with such a tragic misfortune. Even though I have had fatalities I do not believe any of them have been due to this cause. As a matter of fact, I have on several occasions removed diseased bone which exposed the pulsating dura in the immediate vicinity of the olfactory fissure, this in one or two cases was followed by the escape of a quantity of cerebro-spinal fluid. Most of these patients, however, despite my anxiety, recovered without any untoward symptom. Notwithstanding these fortunate sequels, it is nevertheless better to be safe and shun this dangerous region by conserving the olfactory area with its mucosa, since ventilation and drainage should obtain quite as well as though it had also been removed. Following this procedure I know of no condition that reacts more favourably to the silver tampons as an after-treatment than this one.

Hyperplastic ethmoiditis may next be considered, and firstly localized hyperplasia (polyps). The surgery of polyposis and polypoid conditions affecting the ethmoid is so well known that the procedures need not be detailed. I will, however, touch upon some of the more prominent factors concerned in the permanent ablation of these growths. The localized hyperplasias or separate polyps springing from the naso-frontal region and beneath the anterior end of the middle turbinate are usually removed with the snare. Unless, however, the bony attachment is also resected, these are almost certain to return, therefore emphasis should be placed on this phase of the operation in order to ensure a permanent disappearance of the growths. The preliminary resection of a portion of the middle turbinate depends upon the accessibility of these bases to instrumentation. I have often noted in the presence of these moderately large sessile polyps that the hyperplasia is usually confined to the mucosa outside the cells, it being rare to find coexisting intracellular polyps. The one exception to this is afforded by the old chronic cases where the entire labyrinth has long since been diseased. While polyposis of the anterior cells is nearly always extracellular, the opposite obtains with the posterior cells, since one rarely encounters large polyps hanging down into the choana which take their origin from this region. (The large solitary choanal polyp in nearly every instance comes from the maxillary sinus, a fact which I have been able to demonstrate time and time again.) This does not mean that the external mucosa is not also affected, for it, too, shows marked change, but more in the nature of a polypoid degeneration rather than large pedunculated polyps.

When the anterior and posterior labyrinths are jointly affected we have, therefore, both an intracellular and extracellular condition to deal with. As a rule these combined cases have progressed insidiously over a number of years until the entire ethmoid capsule has become a mass of polypoid degenerating mucosa. This is the type of case which is so often associated with asthma and hay fever, or, at least, its symptom-complex can be attributed to the presence of this polypoid tissue. We have found that the only rational treatment from a curative point of view is the complete removal, as far as humanly possible, of the polypoid degenerated tissue.

Several methods lie at our disposal, and we always try to select that one which seems to be particularly suited to the individual case. In this way exigencies such as abnormal anatomical configurations are met with and successfully overcome. Ignoring the ordinary procedures adapted to the simpler conditions, those commonly used in the United States when complete exenteration of the ethmoid is under consideration are the Grünwald, the Hayek, the Mosher, the Sluder, and the Ballenger methods in their various modifications.

CONCLUSION

A brief retrospect over the intranasal methods of operating upon the ethmoid shows us first of all that, to accomplish successfully any operation worthy of the name, an intimate knowledge of the anatomy, both regional and surgical, is essential. This knowledge, like a two-edged sword, cuts both ways, for it not only gives the operator confidence to remove tissue fearlessly, but also the wisdom to exercise caution when approaching a dangerous area. All of us who have concerned ourselves to any considerable degree with intranasal ethmoid surgery must have been convinced that it is impossible in every case to expose completely the mucosa of each and every ethmoid cell—at least, such holds good in my own experience. There exists, unfortunately, no anatomical configuration of these cells which can be used as a normal model, but in operating (despite all the stereoscopic skiagraphs we might have had made) it is the ideal normal that we must keep in mind, and if in the midst of the extirpation we encounter great variations, they must at once be considered anomalous, and we proceed with the operation accordingly. Small wonder is it then that certain deep-lying cells escape our attention, this being the reason why in these cases our ultimate results are not 100 per cent perfect. Indeed, it is now my custom to try to impart this knowledge to those patients of better understanding before attempting any operation, and to state that in my opinion the improvement should be measured by a certain percentage according to the severity and condition of the case—say from 60 to 85–100 per cent representing of course the perfect result. While all of my patients have by no means been restored to their original normal functioning activities, I have, nevertheless, long since become convinced that, when properly executed, the intranasal operation on the ethmoid offers the least dangerous, if not the most facile, opportunity to the patient for relieving him of his distressing and oftentimes dangerous infection.

THE CONSERVATIVE AND SURGICAL TREATMENT OF CHRONIC ETHMOIDITIS *

WALTER HOWARTH, M.A., M.B., F.R.C.S.,
Surgeon to the Throat Department St. Thomas's Hospital

THERE is, I suppose, no subject that is so fraught with difficulties and doubts for the rhinologist as the problem of chronic ethmoiditis. In the first place, the ethmoidal labyrinth varies enormously in anatomical configuration and complexity, so that, like finger-prints, no two ethmoids are exactly alike. In the second place, the position that the ethmoidal capsule occupies in the nasal cavity and its close relations with other sinuses make it difficult to determine precisely the extent of actual disease. The varieties of infection and the reactions of the individual to them provide further stumbling-blocks in the path of exact diagnosis and a proper line of treatment. Moreover, there is a curious lack of unanimity about the classification of chronic ethmoidal disease, so that in many cases it is by no means clear to what particular condition a suggested method of treatment may refer.

It is I think, of the utmost importance that we should at the outset determine what kinds of inflammatory processes we are prepared to recognize as affecting the ethmoidal labyrinth. Few will, I imagine, dispute the fact that clinically we may recognize two varieties: (1) chronic catarrhal inflammation (polypoid degeneration), and (2) chronic suppurative inflammation. Whether these are distinct pathological entities, whether the one can progress into the other, and whether both varieties may be combined in the same ethmoid, are questions upon which there are so many opinions that discussion of them would only tend to obscure our main issue. I am, however, prepared

to take my stand on the existence of these two clinical varieties of inflammation and to deal with the matter from this aspect.

In the first instance let us consider a case of moderate polyposis, this has occurred as a result of prolonged inflammatory irritation of the ethmoidal mucosa, and the polyps are to be regarded as the product of hyperplastic inflammation of the covering of the ethmoid bone. That they are commonly seen on the free edge or from the under surface of the middle turbinate is due to the fact that this structure, which is simply a folded over portion of the ethmoid, is the most prominent feature in the upper part of the nasal cavity.

Then obvious presence may, or may not, lead one to suppose that similar changes may be present in neighbouring tracts of the ethmoidal mucosa, which may for the moment be out of sight, the possibility is not excluded that the source of irritation may be found in discharge from a neighbouring sinus as opposed to the possibility of purely superficial irritation of the mucosa from a variety of definitely local causes.

It is possible for the mucous membrane covering the ethmoid to become primarily diseased and for the hyperplastic mucosa, owing to its favourable milieu of warmth and moisture, to manifest itself as polypus formation. This is the simplest condition, it might, in its early stages, yield to such conservative measures as nasal lavage and the occasional application of mild caustic or astrigent solutions, or in slightly more advanced cases, to the correction of any obstruction which was causing undue congestion in the region of the middle meatus, together with the removal of the polypoid hypertrophy with suitable forceps. This latter procedure should not cause the fact to be overlooked that the inflammatory process has probably spread to the deepest layer of the mucosa, which is the periosteum of the underlying bone, and that the correct removal should always involve a portion of this bone. The snare is an unsuitable instrument for this purpose, and has been abandoned in my clinic for many years.

It is not, however, likely that measures such as these will often suffice, since the cases do not usually come under our notice until they are more advanced and the inflammatory process has definitely spread into the ethmoid cells themselves. When this has occurred it is all but impossible to estimate the extent of the disease and for that reason it is incumbent on the surgeon to proceed circumspectly.

The chief aim should be to ensure a free airway and free drainage. If this is assumed we may expect that a certain number of cases will undergo resolution. Can we attain this object better than by the removal of the middle turbinate? I think not. I am not myself amongst those who regard the middle turbinate with great veneration, and I would far sooner remove it in its hidden polypoid bulk than burrow blindly beneath it in a vague endeavour to open the operculum or break through the bulla. Simple removal of the turbinate without any further intervention will improve the drainage and will cure a certain number of cases.

These conservative measures may suffice for a small proportion of our cases, but in the majority the disease has spread too deeply and the bone has already become friable from osteoporosis. These cases demand more severe measures if a cure is to result.

The problem now is so to plan our operation that definitely diseased tissue is removed with as little interference to healthy structures as is possible. Every surgeon will have his own method of achieving this. Some may rely on repeated "nubbings" with a variety of forceps, whilst others may tent cells open with hooks and remove the debris with a sharp spoon. Others, again, may direct their attention to a particular group of cells that experience teaches them to suspect, and by encompassing their destruction not only remove an area of disease, but also free the ostia of neighbouring sinuses.

Thus far one may go with comparative safety in the belief that little or nothing has been done to destroy healthy tissue or spread infection broadcast through the

* A paper read in a discussion in the Section of Laryngology and Otology at the Annual Meeting of the British Medical Association Cardiff 1928.

labyrinth At this point, then, let us leave this type of inflammation and turn our attention to the chronic suppurative variety

Here we have a different clinical picture in which polypus is usually absent, whilst crusts and purulent discharge take their place, along with a group of symptoms—pharyngeal, laryngeal, or gastric—due to irritation by or absorption of the septic secretion It is clear to our mind that the ethmoidal cells are infected, though how extensively we cannot say

We should therefore once again adopt our conservative attitude and by removal of the middle turbinate do our best to ensure efficient aeration and drainage This may be followed some considerable time later, if necessary, by a limited morcellement of the area from which the discharge appears to come Some cures undoubtedly result from these procedures, and it will be well to allow a fair margin of time for this to occur There will inevitably remain a not inconsiderable residue of cases in which we have done apparently very little to alleviate the patient's symptoms When this impasse is reached in either type of inflammation (and it is at this point that they converge and we may consider them together), we are confronted with the question whether to hold our hand lest worse befall or whether there is a possibility that a more complete surgical procedure may result in the eradication of the disease

We are at the parting of the ways The moment has now arrived when the thought of complete exenteration crosses our minds, and we may well consider what is the best way to achieve it Several ingenious intranasal operations have been devised Attention might be drawn to the merits of Mosher's method in which, beginning at the agger cell, the curette is passed through an anatomical void lateral to the main mass of the ethmoid, and, after hitching up against the anterior face of the sphenoid, breaks the whole ethmoidal capsule into the nasal cavity This might be compared with Sluder's procedure, where the same result is achieved by two skilfully directed cuts with special knives, the one vertically from back to front beneath the turbinate, and the other horizontal from within laterally and just below the base of the skull

Can these or any similar operation effect the desired object? After many years and extended trials of such operations I am driven to the conclusion that by no intranasal procedure that I know of can the ethmoidal labyrinth be completely exenterated

It is for this reason that I wish to bring to your notice and in some way to urge the claim of an external operation If, for the moment, I pass over the possible merit of any transnasal operation such as that recently advocated by Hoigan, it is merely because my experience of it is limited to so few cases

More than twenty years ago, when I had the privilege of assisting Killian in some of his frontal sinus operations, I saw the ethmoid exposed through the external incision, but it was not until 1913, when I saw Dr Conkley operate in New York, that I appreciated how much of the ethmoid could be dealt with through a very small external incision Since that date I have practised a similar operation, in some ways modified and in some ways extended, in an ever-increasing number of cases

I know that there is nothing new about an external operation, I merely claim that it has not been, and is not, performed nearly so often as it should be, and that in obstinate cases it gives a considerably higher percentage of cures than any other operation I have employed it for fifteen years in purely ethmoidal cases, and, as I regard the ethmoid as the key to the frontal sinus, it naturally has formed the basis of my frontal sinus operation.

Through a very small incision in the delicate skin, just internal to the inner canthus, which leaves an almost invisible scar, practically the whole ethmoid can be dealt with, and particularly the fronto-ethmoidal and orbito-ethmoidal cells which are so often at fault, and which tend to keep up the ethmoidal disease These cells cannot be safely and satisfactorily removed by the intranasal method

If an infected high ethmoidal cell is found to be producing a mound in the floor of the frontal sinus, and is

affecting this cavity, it is the work of a few moments to remove a portion of the floor of the sinus, and thereby improve its drainage Moreover, it gives excellent access to the cells of the superior meatus, and especially to that large posterior cell which is plastered on to the anterior face of the sphenoid and which so often remains unopened by any intranasal procedure It is always quite remarkable to see how many cells remain unopened after what was thought to be a complete intranasal exenteration

I do not wish to claim too much for this operation, for there remains a small percentage of cases in which apparently we cannot remove every infected cell, and these cases, though relieved, are not cured I can only say that after an extended experience I regard this operation as of the utmost value, and the main point that I should like to make to-day is that, in well-established cases, the possibilities of the external operation should not be lightly dismissed or its performance unduly delayed

THE HEREDITY OF DEMENTIA PRAECOX.

BY

W S JAGOE SHAW, M.D., B.Ch.,
LIEUT. COLONEL, I.M.S. (Ret.)

LATE MEDICAL SUPERINTENDENT CENTRAL HOSPITAL FOR MENTAL
DISEASES, POONA, INDIA

PRACTICALLY all authorities agree that, in common with other varieties of insanity, some defect in the heredity of the individual is at all events a predisposing cause of the dementia praecox (schizophrenia) from which he suffers. Given this "predisposition" it is further generally assumed that some additional factor is necessary for the actual lighting up of the psychosis, and that this necessary exciting cause may be one of apparently very slight degree if the predisposition is intense. In spite, however, of the most eager statistical research into the histories of tainted and untainted stocks, we know at the present date no more than this about the etiology of dementia praecox. The difficulties in the way of any accurate conclusions are apparently insurmountable, and the results of the inquiries which have been made show little similarity the one with the other. The long intervals between human generations on the one hand, and the unreliability of "family" information on the other, are the chief obstacles to conclusiveness. Further, inquiry is obviously useless except among the educated classes, but here secretiveness as to any known taint is especially pronounced. Then, again, the question is unsettled as to what abnormality is to be considered a "taint"—many writers include genius, and some immorality!

Kraepelin¹ considered "with all reserve" that the disease, though often "familial," was the result of an auto-intoxication due to a "disorder of metabolism," basing his theory on the fact that the first symptoms tend to appear at puberty and adolescence, and his views have received support from the work of Mott,² Lewis,³ and Gibbs, among others. It may, however, be very reasonably contended that the degenerative changes found in the sex glands are secondary to some deeper and earlier defect in the organism.

My experience of the peculiar incidence of dementia praecox among the Parsees of Bombay compels me to the opinion that "inbreeding" is a very definite cause of the disease. By "inbreeding" I mean, as the dictionary puts it, "breeding in and in"—not merely the occasional mating of cousins, especially of those of the first degree. The experience of the ages has led to various rulings against the marriage of cousins. These have been many, but I would mention especially the prohibitions of the Levitical degrees, of the Roman Law, of the Council of Agde (A.D. 506), and of the Canon Law, as evidence of this experience, as also the enactments of many American States at the present time.

Clouston⁴ when discussing his "insanity of adolescence," which approximates to the more recently differentiated dementia praecox of Kraepelin, refers to its marked incidence in Newhaven, and to the notorious "frequency of insanity among the old families of the Society of Friends,

the most self-contained and virtuous of all religious sects," which, I may add, undoubtedly discouraged marriage outside the limits of the society. The conditions at Nanhaven are similar to those of most remote seaside villages in Scotland and Ireland, in which dementia praecox is relatively common.

The Parsees constitute a small and very clearly differentiated group in the Indian population, and among them intermarriage with outsiders, and proselytism, are strongly discouraged. They are the descendants of the Persian Zoroastrians who came over in the eighth century on the conquest of their country by the Mohammedans. These settled in the small island of Diu off the south coast of Kathiawar and the adjoining mainland, and gradually spread over the neighbouring districts of Kathiawar and Gujerat, being, as a rule, hospitably received, and their abilities utilized, by the Hindu and Mohammedan rulers of the States. To this day their language is Gujerati, which, owing to their activities, has become the commercial language of Bombay, far to the south. At first (and to some extent still) they were cultivators of the soil, but later on their peculiar aptitude for commerce came to the fore, and at present the Parsees are the richest race in the East considering their numbers.

In all India at present there are about 100,000 Parsees, and of these about nine-tenths live in Bombay Presidency (which includes Gujerat and Kathiawar), the remainder being scattered widely about India as traders in the principal towns. Their religion is a very strict monotheistic Zoroastrianism, popularly referred to as fire worship. In a short note such as this it is impossible to enter into the teachings of Zoroaster, but the faith inculcates sobriety and benevolence as first principles, with the prospect to the sinner of a very horrible hell or bliss. The Parsee's chief occupation, as I have said, is business, and for this his capacity is notorious. I have never seen a Parsee beggar, and the large hospitals and similar institutions built by the liberality of Parsees in Bombay bear convincing evidence to their benevolence. From the Western point of view the Parsees are far more in touch with our civilization than any other Indian people, and a large proportion of their well-to-do merchants spend a good deal of their time in Europe. In their treatment of their womenfolk especially, they, of all Indians, approximate closest to European ideals. It is notoriously difficult to get at the correct family histories of mental cases in England, and I must confess that I found it impossible among Parsees, whose jealous family secretiveness is proverbial. Not only was one countered by denials of facts which one knew through other sources, but any inquiry on these lines was apt to be considered "insulting" to the family, owing, probably, to the partial absorption of European ideas. At the same time, I could not help noticing that a large number of my patients were closely related. The average Parsee can give one a list of his cousins to the fifth or sixth degree—if he so wills—and refers to all degrees equally as "cousins." As I have pointed out in my *Clinical Handbook of Mental Diseases* (Butterworth, 1925), the marriage of cousins is usual among the Parsees of Bombay, and this custom has gone on since they reached India in the eighth century. It certainly attains its object in "keeping the money in the family," though, owing to it, the Parsee population of Bombay city might now almost be considered as "the family." Of course it is possible that some families may not carry out this custom, but it is generally admitted by Parsees.

The original number of refugees from Persia could not have been very large, but the figures have been most variably stated, and I have not been able to find any reliable statistics on this point. Of the Zoroastrians left in Persia at the time of the eighth century migration the descendants in 1923, according to Sir Percy Sykes,* numbered only about 10,000, and he remarks in regard to the present-day Persians

Unfortunately the custom prevails of marrying cousins in order to prevent the property going out of the family, and also because a relation will naturally be happier than a stranger in the house of her mother-in-law. The results are very bad from a physical point of view, as has been proved in many parts of the world. Persians are loath to give up their old customs, and it is still usual for brothers to arrange intermarriage on the largest possible scale, cases being common of large families intermarrying entirely with their cousins.

Unfortunately there are no statistics of insanity in Persia, and those of India are not worth any consideration, being obviously inaccurate. I have, however, no doubt whatever that the incidence of dementia praecox among Parsees is peculiarly high. The following figures show the types of mental disorder in my last 100 Parsee admissions at the Central Hospital for Mental Diseases, Poona, and of my last 50 private cases.

	Hospital Cases			Private Cases		
	Male	Female	Total	Male	Female	Total
Dementia praecox	35	17	52*	13	11	24
Mania-depressive	11	6	17†	1	2	3†
Insanity with epilepsy	3	0	3	2	1	3
Dementia (secondary)	10	11	21	4	3	7
Paranoia	1	0	1	1	0	1
General paresis	1	0	1	2	0	2
Insanity due to ganja (cannabis indica)	1	0	1	—	—	—
Idiots and imbeciles	4	0	4	5	5	10
Totals	66	34	100	23	22	50

* Including all varieties.

† Including involuntional melancholia.

In addition to the above I would note 11 cases of epilepsy and 15 of the psychoneuroses.

Some of the above cases grouped under secondary dementia were probably originally schizophrenics, but the history given was too vague for any such diagnosis. I was rarely consulted about cases of mental deficiency unless the condition was such as to warrant some hope of recovery or to require hospital care, but have seen many obvious defectives, incidentally, in Parsee families. Many of the cases grouped under other heads showed praecox symptoms, and the recovery rate suggests that these may have been really cases of that disorder.

The percentage of discharges as recovered among these Parsee hospital cases was 6, although the annual average for all classes was just over 50 per cent,* and it was a common subject of inquiry among members of my staff as to why no Parsee ever recovered.

Though their admissions show a high proportion of dementia praecox I have no reason to think that insanity in general is especially prevalent among Parsees. Inquiry is very difficult as most, even of the Parsee medical men, object to the term "insane" being applied to one of their race.

The incidence of dementia praecox among Parsees is peculiarly noticeable in India, as it is a comparatively rare disorder among Hindus, and is rarer still among Mohammedans. Among these two groups the disorder occurs mainly in the educated classes, or rather in the persons of boys who have undergone the intensive system of education or memory training by which only can an Indian hope to obtain admission to Government service. Next to the Parsees, the group or race in which the incidence of dementia praecox is, in my experience, highest among the domiciled Anglo-Indian community.

I desire to bring to notice the fact that in the Indian Parsees we have an example of a sober and industrious race, sprung from a small community of Persian refugees of the eighth century, who have very rarely intermarried with outsiders, or proselytized, whose environment is far superior to that of most Oriental races, and who show a peculiarly high incidence of dementia praecox.

Of course I quite realize that, granted the facts I have stated, it will be argued that the "taint" must have existed among the original refugees. Such a view, however, simply begs the question. However difficult it may be to obtain evidence of the original "taint," such taint is easier of proof than is, for instance, the conception that in the admixture of similar germ plasmas lies the

* This high percentage is largely due to the high recovery rate of ganja cases, of which many were admitted from among the lower classes of Hindus and Mohammedans.

real cause of the trouble. It is curious that the majority of inquirers, who discredit the reputed ill effects of consanguineous mating, consider any suggestion of it similarly "begging the question," and this view of the matter is either ignored or derided by recent writers on the subject. The idea is, for instance, only touched upon at one point by Myerson,⁸ who writes:

I scoff at the implication that because the paternal great grandfather and great grandmother were first cousins that we have any clue whatever to the gross defect in their great grandchildren, their father and mother being superior people.

He would probably similarly scoff at the suggestion that the continuous mating of cousins—irrespective of any imaginary common "taint"—could tend to produce dementia praecox, but such a result is surely possible.

Some writers accept as ancestral "taints" such conditions as, for instance, heart disease, blindness, and neuralgia. These inquirers do not apparently realize that we are all imperfect, and that the fact of such imperfection in an ancestor is not, after all, a satisfactory proof of the likelihood of mental disease occurring in a descendant.

L. Rudin⁹ considers that dementia praecox is transmitted according to Mendel's law, and is increased by inbreeding. Myerson,⁸ after able analysis of many family groups, agrees with Rosanoff,¹⁰ Jolly,¹¹ Luther,¹² and Krueger,¹³ and states that "dementia praecox breeds true and in an ancestor is usually followed by dementia praecox in the direct insane descendant. Moral imbecility, feeble-mindedness, and epilepsy are also found in the descendants and frequently in combination with dementia praecox." In other words, he considers dementia praecox a Mendelian recessive character. The writers I have mentioned find, further, that insane descendants of persons who have suffered from the involution psychoses are cases of dementia praecox, as are also often the insane descendants of manic-depressives. As Myerson⁸ puts it, "All roads seem to lead to dementia praecox and from thence to imbecility. As the disease gets worse from generation to generation it ends in dementia praecox." Dementia praecox in an ancestor, on the contrary, does not appear to be a precursor of manic-depressive in the descendant, but as deterioration becomes more marked dementia praecox appears, and I can imagine no condition showing such obvious all-round degeneration as this syndrome presents.

If many of the original refugees had been schizophrenics, it is very doubtful if a Parsee race would now exist in India. But 100,000 do exist (among some 320,000,000 Indians of all races and classes), and include a large proportion of very able persons. At the same time most of those who become insane suffer from dementia praecox, and the custom of the marriage of cousins has persisted since the eighth century in this community, which is not a large one. Judging by the results obtained by Myerson and others, it is therefore probable that any original taint which, by its transmission through inbred generations to present-day Parsees, might breed in them dementia praecox, was itself a very much less serious form of mental disease, or, at best, if indeed it could be classed as such at all.

Our present-day differentiation of mental deficiency from insanity is surely merely one of convenience, and few will, I think, argue the impossibility of the consideration of schizophrenia as being a variety of the former rather than of the latter group of disorders. In most cases the degenerative tendency appears to be inborn in the individual.

As I have previously written, the disorder has a predisposing and an exciting cause. In the case of the Parsees the former is contained, presumably, in the heredity, but it is, I think, a question whether the heredity acts as a cause solely by means of an inherited taint or whether consanguineous mating in some way itself lessens resistance to the stresses of life, and helps to produce the disorders of metabolism that are possibly the most usual exciting causes of the breakdown. As White¹² puts it:

Every individual born into the world has, if it could be determined a definite potentiality for development. The force or the impetus which starts it on its path is sufficient to carry it a certain definite distance in the subject of this disease the original impetus has been weak and when its force is spent [mental] development stops and the retrograde process is hastened or inhibited by some special physical or mental stress occurring at the critical point of puberty and adolescent evolution.

What is, however, the cause of the failure to carry on? Tredgold¹⁴ comes to the conclusion that feeble-mindedness results from a vitiated germinal vitality which prevents normal development, and most authorities are, as Myerson⁸ writes, "firmly convinced that there is a familial transfer once of certain types of feeble-mindedness, and there is very distinctly appearing the belief that these familial cases originate in injury to the germ plasma." One may perhaps speculate on the kind of injury he adumbrates. It is possible that "similar" germ plasmas may be in some way detrimental to each other.

Most authorities insist on the view that the marriage of cousins conveys no danger to the offspring, if the common stock is sound. There is, however, no reason to suppose that the original refugees were in any way more unsound than any similar group, and, as no stock appears to be absolutely sound, the contention that consanguineous mating should ever be approved is very doubtful, as it must tend to intensify in the offspring any taint common to both parents. Nowadays at all events, the common Parsee stock is seriously tainted with dementia praecox, and the propriety of the abandonment of the custom of the mating of cousins should be definitely considered by them. Perhaps research into the results of such mating may be possible in some other field, but I am certain that little further result can come of inquiry in this one, unless it is carried out by a Parsee of an unusually altruistic type. The subject is one of immense importance sociologically and eugenically, as dementia praecox is the form of mental disorder which, owing to its relative incurability, keeps our mental hospitals full.

AUTO-TRANSFUSION

WITH THE ACCOUNT OF A CASE

BY

H. B. DEVINE, M.S. MELBOURNE,

HONORARY SURGEON TO IN-PATIENTS, ST VINCENT'S HOSPITAL, AND ASSISTANT LECTURER IN SURGERY, MELBOURNE UNIVERSITY,

AND

VICTOR J. KINSELLA, M.B., CH. M. SYDNEY

ALTHOUGH auto-transfusion may often be the best and most readily available means of saving life in a surgical emergency it has not received the notice which it deserves, and the object of this communication is to draw attention to so useful a measure. Our interest in it was aroused by the following case:

A boy aged 12, fell from the balcony of his home to the pavement beneath. He was perfectly conscious although he had a very local assured fracture of the skull, subsequently revealed by x-ray examination, and both bones of each forearm were broken. His pulse rate was slow. The abdomen was soft and not tender and the patient assured us that he had received no injury in that situation. Under ether anaesthesia the fractures of his forearms were reduced. A few hours later signs of severe intra-abdominal haemorrhage definitely showed themselves. He rapidly became blanched and pulseless, and was in a desperate condition when brought to the operating theatre. The haemorrhage came on insidiously because its early signs were doubtful and obscured by the other injuries and the anaesthesia.

Always ready in our operating theatre, even to the smallest detail is what we call our "transfusion tray." Realizing the possibility and value of auto-transfusion in such a profound bleeding this ready-to-use tray was requisitioned, and proved the great value of such a precaution because of the short time at our disposal. The abdomen was opened by Mr. Devine, this found to be full of fluid blood containing a few clots, this was quickly ladled out and dropped into citrate solution. Mean time a vein had been opened by Dr. Kinsella and reinfusion of the citrated blood was begun even while the blood was being removed from the abdomen. The source of bleeding was found to be a tear near the pedicle of the spleen. The abdominal wall showed no sign of trauma the injury having been inflicted apparently in some indirect way.

The bleeding appeared to stop as the transfusion was given and gauze packing was gently introduced over the tear. Thanks to the large quantity of blood which had been infused a dramatic change now took place. The patient became quite warm, his colour improved and the pulse became easily palpable. The packing was watched for a time with a degree of equanimity impossible in the early stage of the operation. The abdomen was closed and the patient returned to bed. No reaction followed and convalescence was rapid and uneventful.

This gratifying result suggests the advisability of using reinfusion in the more severe cases of acute intraperitoneal bleeding, in which the patient urgently needs an addition to the circulating fluids. It is not uncommon to see such patients given various solutions by different routes while the most suitable fluid of all their own blood, has been thrown down the sink. Experience has shown that blood can be safely reinfused, even after lying in the abdomen for a considerable time. The question of changes taking place in the blood does not arise in the acute haemorrhage for which this measure is advocated, for the blood is comparatively fresh in these cases. The hurried subcutaneous saline given in the operating theatre, or perhaps in the ward may sometimes lead to undesirable infection, but we have not seen an infective complication following an intravenous injection. Probably the reason is that blood is not only an unsuitable medium for the growth of bacteria, but has marked bactericidal effect, as shown by Altmouth Wright, Culebrook, and Storer.¹ It is known that germs may enter the blood stream, and their growth be kept in check until they are finally excreted by the kidneys or by the liver. The slight infection possibly present in acute ruptured ectopic gestations is not necessarily, therefore, a contraindication to reinfusion.

A German gynaecologist, Thies is given the credit of introducing auto-transfusion in 1914. Burch published a survey of the literature in 1923.² Up to this time 164 cases had been reported, 160 of these in Germany, made up chiefly of acute ruptured ectopic gestations and severe injuries and wounds with haemoperitoneum and haemothorax. In these cases there were 14 post-operation deaths, only one of which could possibly have been caused by an infusion. The method was proved to be valuable and safe.

Sir William Taylor of Dublin suggested a further use for reinfusion in splenectomy.³ This operation may be very difficult, and attended by much blood loss and shock, especially when the spleen is large and the patient is already suffering from blood dyscrasia. As soon as the spleen is removed it is held by an assistant over a vessel containing citrate solution. The clamp is removed from the pedicle, and the blood is allowed to drip into the vessel the flow being aided by squeezing the organ. This citrated blood is then reinfused.

Loyal E. Davis and Horner Cushing found reinfusion a most valuable and life-saving device in the major cranial operations.⁴ The blood is removed from the field of operation by suction rather than by swabbing, citrate solution is sucked up from a basin, swabs and towels are wrung out into the solution, and the mixture is re injected. The authors show impressive graphs of very severe surgical shock in which immediate and marked improvement followed this reinfusion.

Scant attention has been paid to this method in British literature, in discussions on blood transfusion it is summarily judged and condemned without trial. Thus, in a recent discussion its only notice was a brief reference by Sir Humphry Rolleston to Blain and Brines, who believe that reinfusion is inadvisable.⁵ But Blain and Brines record no more than their beliefs give no reasons, and have apparently no experience of the method.⁶

Technique

In giving intravenous injections of large volumes of fluid every effort should be made to prevent those reactions which the patient so often suffers after this treatment. In auto-infusion we are relieved, of course, from every anxiety about the compatibility of the donor.

Probably the next most important point in giving any intravenous injection, whether of blood or of saline or of glucose, is to exclude not only living but also dead organisms. The importance of keeping out dead bacteria is once suggested by experience with intravenous vaccinations—for example, in the treatment of typhoid

fever and of rheumatoid arthritis. The reactions following such treatment and the usual post-transfusion reactions are similar in every way. They appear a few minutes to half an hour after the injection, the patient feels cold and has a rigor, which may be very severe. In practice, therefore, it is not enough that the water used in making the solution should be sterile. It should be freshly distilled before sterilization. Whenever possible it is our practice to have the water distilled on the same day that the injection is given. For emergencies a supply of water, first distilled, then sterilized and sealed, is kept on hand. This should keep indefinitely without bacterial contamination but, as a routine, it is boiled before use. In two and a half years we have experienced only three marked rigors after infusion of blood or glucose. In one of these glucose dissolved in ordinary tap water had been given in an emergency, and in another blood transfusion had been performed with sodium citrate dissolved in the chemist's stock distilled water. The importance of using freshly distilled water in blood transfusion has not been sufficiently emphasized in the literature, this probably accounts for the unduly high proportion of reactions which follow the use of citrated blood. Even Lewisohn the great protagonist for this method, reports 23 per cent of reactions.⁷

Burch states that the use of citrate solution in auto-transfusion is not necessary, for the blood has been given mixed with saline, or defibrinated, or even unmodified. But the citrate method is the most certain, for it eliminates the possibility of clotting, which might cause serious delay or even failure in desperate cases. Moreover, it enables one to give the infusion slowly, and this point is most important, not only to avoid overloading the heart, but also to help to prevent undesirable reactions. French observers (Cruchet and Ragot) declare that even if agglutination and haemolysis take place, no ill effects need follow if the injection is given slowly.⁸ An ounce a minute is the maximum speed permissible when using compatible blood or a suitable solution.

Memoranda :

MEDICAL, SURGICAL, OBSTETRICAL

TRAUMATIC ASPHYXIA

TRAUMATIC asphyxia is rare, and some of the standard text books on surgery and medical jurisprudence do not even mention it. The following details of a case may therefore be worthy of record.

In 1926 a tall powerfully built young man aged 28 presented himself at my consulting room. His face was deeply cyanosed and the subconjunctival tissue of both eyes was suffused with bright red blood giving him a most startling appearance although he did not appear to feel ill and had walked half a mile to see me. He stated that except for a headache he had been in good health when he went to bed two nights previously. He awoke the following morning in his present condition. He and his family absolutely denied that he was subject to fits and they could give no clue as to the cause of the seizure. He mentioned that he had suffered from a similar though less severe attack two years previously. He had consulted me seven months before for a small subconjunctival ecchymosis of one eye for which he could ascribe no cause.

On examination it was found that above a line running round the neck from the level of the upper margin of the cricoid in front to the fifth cervical spine behind, the skin of the head and neck had a deep cyanotic tint, with a few small points of ecchymosis in the scalp behind the ears and over the cranium. The mucosa of the palate tongue and pharynx was also of a purplish blue and showed several small extravasations of blood. Below the line of demarcation the skin was perfectly normal. There was no mark of any constricting band.

In the absence of information as to the mode of onset I could not explain the condition until a few days later I learned from

neighbours that the patient had suffered from occasional epileptic fits since boyhood. On further inquiry the brother with whom he shared a bedroom admitted that he had been awakened in the early hours of the morning by his brother having a fit. I found also that the patient slept in an ordinary shirt with a rather tight collar band fastened by a stud. The upper margin of the collar band coincided with the line of demarcation of the cyanosis. The case then appeared to be one of traumatic asphyxia, the strangulating agent being the unyielding collar band operating during the congestion and partial asphyxiation of the epileptic fit. An interesting sequel was the development of severe exophthalmic goitre in the patient's mother aged 60 within a few months of the shock occasioned by her son's seizure.

I sent an account of the case to the late Professor Harvey Littlejohn of Edinburgh who expressed the opinion that it was undoubtedly a case of so-called traumatic asphyxia caused by the collar band compressing the jugulars together with the partial asphyxia, high blood pressure, and fixation of the chest caused by the epileptic fit."

The few other cases of recovery which have been recorded have occurred likewise in patients between the ages of 15 and 35. The usual cause is severe compression of the thorax and abdomen sufficient to prevent respiration for an appreciable length of time, as when individuals are crushed in dense crowds. In these cases the discoloration extends to the root of the neck and ceases more or less abruptly about the level of the clavicles. A striking example of this was illustrated in an article by Beach and Cobb in the *Annals of Surgery*, April, 1904. Betham Robinson also reported a case in the *British Journal of Surgery*, 1914-15, vol. ii, p. 173, in which the discoloration ended abruptly half-way down the neck at a line corresponding to the top of the collar. On this occasion the thorax was crushed by a lift, and the collar acted, as in my case, as the actual agent of strangulation of the congested and swollen neck. So far as I can ascertain my case is the only one on record which did not originate in compression of the chest and abdomen by external violence.

The limitation of the cyanotic discoloration to the face and neck is due to the absence of competent valves in the jugular and facial veins. This, under certain conditions, permits mechanical over-distension of the smaller veins and capillaries with stasis of de-oxygenated blood. The cyanotic tint of the skin depends on this latter factor and not on petechial haemorrhages into the cutis. It is usually stated that there is no extravasation of blood except under the conjunctivae. In my case, however, there were several distinct extravasations into the cutis of the scalp and under the buccal mucosa.

POLYSEROSITIS IN LATER LIFE

POLYSEROSITIS or Concato's disease, is a widespread affection of the pleurae, pericardium, mediastinum, and peritoneum. It occurs, as a rule, in young subjects, and the causal factors are unknown. The following case appears worthy of record in that the patient was aged 60, he had been an habitual drunkard.

The patient was admitted to hospital complaining of abdominal pain, progressive weakness, constipation and vomiting. He was a thin wasted man, with a dirty sallow complexion and watery eyes. His facial expression denoted anxiety and continual pain. His skin was dry and hot, the temperature was 100° F. and the pulse rapid. He was dyspnoeic. The duration of the illness was said to be four years, during which time he had had attacks of pleurisy. There was no history of rheumatic fever.

Upon examination his abdomen was found to be much distended, and the movement poor. There was a generalized doughy resistance to palpation and vague, irregularly defined masses could be felt. Percussion showed scattered areas of dullness and resonance. There was shifting dullness in the flanks. Neither the liver nor the spleen was palpable. No abnormality was detected upon rectal examination. There was a systolic retraction at the cardiac apex which was fixed, and retraction in the eleventh interspace posteriorly. The cardiac impulse was marked from the third left space to the apex. The area of cardiac dullness was increased. There were no murmurs. There was poor expansion generally over both lungs. Resonance was impaired, with indications of thickened pleurae especially at the right base. Vocal fremitus was diminished particularly at the right base and vocal resonance was diminished generally. The breath sounds were much impaired, but there were no accompaniments. Generalized arterio-sclerosis was present and the blood pressure was high. The urine was increased in amount and there was troublesome nocturnal micturition. The specific gravity of the urine was 1005, the water was pale, the urea content was low, and there was a slight trace of albumin.

Diagnosis of this case was easy in view of the adherent pericardium, the evidence of old thickened pleurae, the doughy abdomen with its areas of dullness and resonance and shifting fluid, the chronic interstitial nephritis, with the history of chronic alcoholism.

The course of the illness in hospital was short. The patient was in considerable danger from uraemia, which, however, did not develop. Symptomatic treatment only was possible, and paracentesis was performed when this was indicated. The evening before he died the patient developed Cheyne-Stokes breathing. Death resulted from exhaustion and cardiac breakdown.

At the necropsy there was found an adherent pericardium with thickening of the mediastinal tissues. The heart was greatly hypertrophied but there was no valvular disease. The pleurae were thickened and adherent and there was a small collection of fluid on the right side. The pleura was adherent to the diaphragm, the lungs were otherwise sound. The peritoneum was much thickened and pearly white, the omentum was rolled transversely across the abdomen. Adhesions of all degrees were generalized throughout the abdomen, binding the intestinal tract and causing considerable linking. Much free fluid was present and there were many collections of encysted fluid. The liver was of the sugary character and contracted. The capsule stripped with some difficulty, it was adherent to the diaphragm and slightly fibrotic. The spleen showed similar changes. The stomach was characteristic of chronic gastritis. Adhesions involved the stomach, pylorus, gall bladder and pancreas. The caecum and appendix were greatly thickened. The kidneys were small, each weighed 2 oz. They were red and the capsules were adherent. On section they were found to be tough with a reduced cortex and prominent vessels.

In so late a case of polyserositis there was, of course, no difficulty in diagnosis, in early stages the diagnosis cannot be easy. It is hard to believe that this generalized polyserositis could have been caused by chronic alcoholism, though alcohol is a certain factor in the production of perihepatitis and diffuse peritonitis, with interstitial nephritis. In this case the disease may have spread from a local area. It is held by some that interstitial nephritis, by its toxic effect upon the patient, may cause polyserositis, some physicians consider that, in the absence of jaundice, "sugar-ice" liver is associated with, and the consequence of, interstitial nephritis.

B. GORDON DELSTON, M.D.

TOTAL CONCEALED ACCIDENTAL HAEMORRHAGE SIMULATING OVARIAN TUMOUR

SINCE total concealed accidental haemorrhage only occurs on an average once in fifteen thousand pregnancies the following case appears worthy of record.

A multipara with five children was admitted to hospital as an acute abdomen with the history of an operation for perineal repair three months previously at a metropolitan hospital where she was not considered pregnant although two periods had been missed at that time.

After five months amenorrhoea without any other symptoms of pregnancy—though these had been very marked in former gestations—the present illness began with a week's malaise and then sudden sharp pain of a stretching character which was referred to the lower part of the abdomen especially on the right side. The patient's normally rather sallow face showed little loss of colour, but was of the typically abdominal type, the pulse was only 88. The abdomen was distended and rigid with an indefinite fluctuating tumour extending above the umbilicus and to the right side. The os uteri was hard and "pin point" and there was no bleeding, both fornices were intensely tender and there was a hard mass in Douglas's pouch. The most obvious symptom was the pain which was constant and intense. The diagnosis of a twisted ovarian right-sided tumour with haemorrhage into it appeared to be justified by the presence of a painful swelling after five months amenorrhoea without other signs of pregnancy, the mass in Douglas's pouch was thought to be the retroverted fundus.

At the time of operation forty-eight hours later a trace of blood was found for the first time on vaginal examination. The abdominal incision exposed a thin walled, flabby, greyish-red tumour extending from the right side of the pelvis to beneath the liver. The tumour was still thought to be ovarian and it was only after drawing off about two pints of blood from the apparently thin walled cystic tumour that its true nature was revealed by feeling the foetus. The placenta situated over the internal os and the foetus were removed through an incision in the uterine wall which was so thin that only one layer of sutures could be introduced. Injections of hot saline solution and pituitrin directly into the uterine wall caused good contraction and the subsequent recovery was uneventful.

Proof that the uterine wall had recovered its thickness and tone was seen recently in a subsequent labour of nearly a week's duration, a 12 lb full-time child had to be delivered by internal version.

BRAIN AND MIND

PROFESSOR R. J. A. BERRY'S treatise, *Brain and Mind*, falls naturally into two divisions—the larger part of his work, which is devoted to a description of the structure and functions of the human nervous system, and the part in which he seeks to apply this knowledge to the solution of present-day psycho-sociological problems.

Professor Berry's worth as an anatomist and histologist is sufficient warrant for the scientific accuracy of his descriptions. He proceeds from the consideration of the simplest phenomena of the nervous system to the more complex, making full use of the findings of modern histological research, associated especially with the names of Golgi and Cajal, Shaw Bolton, and Watson. His presentation of the subject is clear and comprehensive, in its avoidance of non-essentials and its skilful continuity it makes pleasant reading. Many of the numerous diagrams and photographs illustrating the text are original, and the rest are eclectically taken from Luciani, Morris, and others. The unit of nerve structure—the neuron—is described, and its functional working considered. Particular stress is laid on the importance of the short interneuronal neurons in the interpretation of the phenomena of mind and its aberrations. The developmental history of the autonomic and the cerebro-spinal nervous system and that of its component parts are traced. Throughout the histological descriptions are clear and authoritative. The sensory and motor pathways in the cord and brain are outlined. Professor Berry speaks of the olfactory sense as of little importance in the human economy. The extensive ramification of the olfactory memories, however, probably accounts for much in the life of man as yet unexplored, but of undoubted psychical significance. The importance of cortical structure in health and disease is emphasized, and the arguments for regarding the granular, association and commissural neurons as the physical instruments of mind are set forth. Professor Berry's anatomical observations lead him to believe that the study of cortical histology is of supreme importance in the interpretation of aberrant mental phenomena. The thalamo-striate and the ventricular systems are adequately dealt with. The acquisition of speech and its loss by disease are discussed in a chapter in which the author insists on the need for a fuller study of cortical histology if the problems of aphasia are to be rightly apprehended.

It will be seen from what we have said that this part of Professor Berry's work calls for nothing but praise. In the second part there is much that is helpful and suggestive, much that is debatable, and a number of statements with which many of his readers will wholly disagree. In drawing attention to the importance of neurone deficiency as the basal factor of much mental disease, apart from the anemias proper, Professor Berry does a real service. His method of examination of suspected anemias deserves close study. In addition to carrying out the routine clinical examination he estimates the cubic capacity of the brain, the standing and sitting stature, the weight, the grip and vital capacity, and the Binet and Porteus reactions. These, in his opinion, form the minimum for an adequate ascertainment of the presence of such defect. The technique is fully described.

"No neuron, no mind," is the ever-recurring theme of these pages. Medical men will not feel inclined to dispute this tenet. Every person of intelligence regards the cortical grey matter as the chief organ of psychical life, and the activity of its tissues as the medium whereby physiological sensations are converted into psychical reactions, but it is a far cry from such a belief to complete acceptance of a doctrine which would identify the physical with the psychical. And yet, says Professor Berry, "If the ideas are not in the brain cells, where are they?" Elsewhere he states that neurologically it is quite impossible for a dream to be an inspiration towards a higher form of intellectual and spiritual life because it is compounded only

of previous experiences, not future ones." This will surely strike many readers as a *reductio ad absurdum*. Neurologically it is impossible for a dream to be a dream. A dream is a psychological phenomenon, not a neurological one, although it may well be that its physical basis is neurological. The following quotation from the *British Medical Journal* of March 3rd, 1923, appears in the foreword to Professor Berry's book: "The re-establishment of the spiritual interpretation as the supreme interpretation of our universe is in no way inconsistent with the mechanistic interpretation of the living body." The wisdom of these words is not to be gainsaid, but it seems strange that Professor Berry, who apparently denies the reality of "experience," should quote them.

GYNÆCOLOGY AND OBSTETRICS

It is four years since Dr J. S. FAIRBAIN published his combined volume on *Gynæcology with Obstetrics*, and during this period the book has taken a definite place amongst the standard British textbooks on the subject. In the second edition, which has recently been published, there is comparatively little change of any substantial nature.

The most important improvement is undoubtedly the increase in the number of illustrations, which are for the most part good, and will serve to make the book more interesting and more helpful to both students and practitioners. The text generally has been revised, and in regard to certain subjects in which research has enabled us to make progress, rewriting has been called for—for example the subject of ovarian function. The sections on the development of the early ovum and embryo and the midation of the ovum have been largely rewritten and a number of Professor Teacher's lucid and helpful diagrams have been included, which simplify a subject that the student always finds difficult. A brief outline of treatment by radium has been included owing to the important part which it now plays in gynæcological therapeutics, but we are disposed to regard this section as too brief and meagre to be of any real value in guiding the practitioner. The statistics of maternal and infant mortality have been brought up to date, while references are also made to more recent administrative enactments such as those governing the registration of stillbirths and the notification of puerperal prexvia.

The favourable opinion which we formed of this book upon its first appearance is fully confirmed upon renewing acquaintance with it in this second edition. As a student's textbook it is adequate, but it is probably practitioners and those who are engaged in teaching nurses or students to whom the volume will make its chief appeal. There is always something suggestive and thought-stimulating about Dr Fairbairn's writings which makes them particularly valuable to those who are thinking about matters gynæcological and obstetrical, and in this respect the volume is no exception to the author's other writings.

ANATOMICAL FOUNDATIONS

DR LUBOSCH'S *Outlines of Scientific Anatomy*, a translation of which has been published by Dr WOOLLARD, professor of anatomy in the University of Adelaide, is designed to supplement the usual textbook teaching with matter of additional interest. Students, in Dr Lubosch's experience, have a longing for a more stimulating presentation of anatomy, in other words they find the subject dry, and it is for those who suffer from this very common defect—observable not only in connexion with anatomy, but in all forms of study that call for prolonged concentration—that the book has been written.

The table of contents gives a general idea of the material which it is hoped may serve to focus the interest of the student. An introductory chapter explains the extent and content of the conception of science. The part dealing with

² *Gynæcology with Obstetrics*. By John S. Fairbairn, B.M., B.Ch., F.R.C.P., F.R.C.S. Second edition. Oxford Medical Publication. London: Milford Oxford University Press, 1928. (Demy 8vo pp. xxix + 310, 157 figures, 5 plates, 25s. net.)

³ *Outlines of Scientific Anatomy*. By Dr Wilhelm Lubosch. Translated from the German by H. H. Woollard, M.D. London: J. Bale, Son and Danielson Ltd., 1928. (Roy. 8vo pp. xlii + 392, 66 figures, 21s. net.)

¹ *Brain and Mind*. By R. J. A. Berry, M.D., F.R.C.S., F.R.S. Ed. New York: The Macmillan Company. London: Macmillan and Co. Ltd., 1928. (Crown 8vo pp. xii + 606, 139 figures, 31s. 6d. net.)

generalities has chapters on life and its appreciation and objectivation, on the principles of change, the laws of permanence, of form, and transformation, and the transformation theory. The special part deals with man as an individual, as a member of a race, and as a member of a higher category, under which is considered his promorphology, his morphogenesis, and the experimental analysis of the formative processes, including the development of intellectual concepts from experimental embryology. The final chapters deal with histomorphology, extomorphology, and leptomorphology.

Briefly stated, the suggestion is that the teaching of the bare facts of anatomy should be supplemented by references to embryology, anthropology, zoology, biophysics, philosophy, and other subjects. It used to be considered that the obvious practical importance of the study of anatomy was sufficient in itself to rivet the attention of any serious student, without any special prompting. Views have shifted somewhat in recent times, the study of human anatomy from a purely medical aspect is discountenanced, and its relation to biology generally is beginning to be insisted on. There is nothing to be said against the change, but it should be realized that, for students of medicine at least, the practical and utilitarian view of the study remains the important one, and they will wisely avoid anything tending to divert them from the main subject into interesting by-paths.

There is an impression that the present-day student has not such a thorough grounding in anatomy as his predecessors had, and that the altered standpoint from which the subject is regarded is partly responsible. We are glad, however, to note that Professor Lubosch advocates that detailed study of individual structures (of the humerus, for example, as explained on page 126) which is now often regarded as old-fashioned.

FASCIAL GRAFTING

MR H C ORRIN's little book on *Fascial Grafting in Principle and Practice* has a subtitle, provided, one may suppose by the publishers, who, like parents, are apt to think all their geese swans. For this is not "An illustrated manual of procedure and technique", its content would make a valuable contribution to a surgical journal and requires some padding to fill it out to eighty-eight pages. There is a bibliography, but it is very imperfect. Such a reference as "Halstead, *Ann Surg*, Phila," is irritating, of thirty entries only eighteen are dated, and of these twelve are of 1913 or earlier. The author speaks of the "results of his own continued experimental work," but in the chapter summarizing this subject gives no indication as to which is his own and which that of others. For example, he says that oesophageal defects were "successfully repaired by fascial grafts functional and anatomical results appeared equally satisfactory." When he says this without a precise reference, the statement has little value. A very important point, that fascia lata does not necessarily die even when grafted into an area still infected, is illustrated by cases, but it is not quite clear whether they are his own or other people's.

The really useful part of the book is that devoted to a description of the fascia lata, to the technique of its removal and preparation, to its use in the repair of tendons and tendon sheaths, and to the investment of nerve trunks. The directions as to these points are, for the most part, clear, at any rate with the help of the diagrams. The use of fascia lata to form new tendon sheaths is dependent, presumably, on the absence of a tendency for undamaged surfaces of the fascia to adhere provided early movement be instituted, but since the same fascia, when needed for the cure of ventral hernia, "seems to have the power of inducing a growth of strong fibrous tissue" one looks for very dogmatic and detailed guidance in the immediate after-treatment of sheath-formation cases, whereas that given is scrappy and slightly contradictory. Of the use of fascial graft for filling defects in hollow viscera, in the genito-urinary tract, in arterial walls, for

visceroplexy, for diaphragmatic hernia, for arthroplasties, for Dupuytren's contraction, for "trapezius separation," to "support relaxed or paralysed facial tissues," to all of which space is devoted, there is scarcely one example of which it can be said that the directions are adequate, and that is the least that can be expected of a "manual of procedure and technique." The illustrations are for the most part good, but surely an error has crept into figure No 35.

A TREATISE ON KALA-AZAR

THE second edition of Dr UPENDRANATH BRAHMACHARI's book on kala-azar and its treatment was published in 1925. A new book, entitled *A Treatise on Kala-azar*,² by the same author, is based upon the article on this disease contributed by him to Mense's *Handbuch der Tropen Krankheiten* (1926). According to the preface it embodies "all the latest facts known about the probable transmission of the disease by means of the sand fly, the description of dermal leishmanoid, a new form of cutaneous leishmaniasis due to *Leishmania donovani* (first discovered by the author), and the latest advances in the treatment of the disease by means of the aromatic antimonials, some of which were discovered by the author in the course of his researches." Mediterranean infantile leishmaniasis, which was not dealt with in his previous works, but which the author now holds to be identical with kala-azar, has been incorporated in the present volume, but the American disease and local forms are not included, and little is said of the disease in China. The first eight chapters discuss the history and distribution of the parasite, the probable modes of transmission, animal experiments, and the relationship of canine leishmaniasis. In describing the morphology of the parasite it might have been useful for the student if some of the terms used had been defined, and a text figure illustrating some of the rarer forms would have been an advantage. We note that the author adopts the term "parabasal," using this adjective in place of "parabasal granule," a usage which unfortunately appears to be creeping into protozoological literature.

Dealing with transmission the author discusses all the possible means and gives an account of the work in connexion with *Phlebotomus argentipes*. The question remains unsettled, and the author does not appear to be impressed by the arguments which have been brought forward to incriminate the sand-fly. In chapters 9 to 12 an account is given of the clinical course, prognosis, and diagnosis along the usual lines. Under pathology there is little new since Christopher's original description, except that the author lays stress on infection of the reticulo-endothelial system with the specific tissue reaction in the form of appearance of clasmocyte tissue.

The chapters on treatment, and what has been called dermal leishmanoid, are perhaps the most interesting. Treatment since the introduction of urea-stibamine and allied aromatic antimonials has been revolutionized, and the whole subject is very fully dealt with. The appearance of the odd skin lesion occurring in cases about a year after apparent cure with antimonials, first described in 1922, is well set out and figured, and the histo-pathology is given in detail. At the end of this monograph will be found 55 pages of bibliography containing some 1,600 references to the literature.

DIETETICS

IN the preface to his *Handbook on Diet* Dr MARCOVICI explains that he has endeavoured to fill the gap which exists between the full-blown medical textbook and the small volumes dealing with dietetic matters which are intended for lay consumption. We cannot congratulate him, however, upon the success of his attempt. The first chapter—on digestibility of food—contains references which can be comprehensible only to a medical man fairly well versed in the latest vagaries of the classification of the

² *A Treatise on Kala-azar* by Upendranath Brahmachari, A.M. (gold), Rai Bahadur, M.D. Ph.D. London: J. Bale, Sons and Danielsson Ltd. 1928. (8 x 11 pp. xv + 252, 38 figures, 12 plates, 21s. net.)
³ *Handbook on Diet* by Eugene E. Marcovici, M.D. Philadelphia: F. A. Davis Company, 1928. (Demy 8vo pp. viii + 325, 3.50 dollars net.)

types of digestive disturbance, and we believe to such a one only after some difficulty, so badly expressed are some of the remarks. On the other hand, the discussion on the theoretical aspects of cooking is serviceable, and deals with matters which might well receive more attention than they usually obtain. The fundamental aspects of diet, such as the energy value, the degree to which foodstuffs are mutually replaceable, and the elementary chemical facts of metabolism, are treated in a brief and stereotyped manner. Yet surely it is of the utmost importance that these fundamental facts should be understood by the medical man, and appreciated by his patients: they are neither obscure, nor difficult to grasp, and an acceptance of them would help the patient to co-operate with the doctor in carrying out orders. The bulk of the book is taken up by a rather tedious discussion of the special dietary requirements in various diseases. Much of what is said might be left to the imagination, and some at least of the remainder is debatable. The author expresses the hope that physicians may feel inclined to recommend the volume to the perusal of their patients. We can hardly imagine a book that most medical men would be more reluctant to see their patients reading. Even to the well-educated mind the printed word, as such, carries a certain weight, if it deals with the unfamiliar and technical, and the unfortunate doctor would find himself constantly taken to task for not pursuing some course to which, as likely as not, he would feel himself heartily opposed. Again it is unfortunate that Dr. Marcovici has chosen to discuss "gland diet." Medical men are well aware of the very great value of certain gland preparations. They also know that there are few fields in which commercialism and charlatanism reap a richer harvest. The fruit is certainly not yet ripe for lay consumption. On the whole we feel that this volume does little more than make confusion worse confounded.

NOTES ON BOOKS

In their small volume on basal metabolism and its clinical applications, Drs. CLAUDE GAUTIER and RENÉ WOLFF have succeeded in compressing a great deal of useful information. They deal briefly, but effectively, with the meaning and physiological significance of basal metabolic rate, and with the variations met with in health. They discuss the methods and equipment used in research and in clinical work, a considerable section of the book deals with the diagnostic importance of the variations which may be encountered in disease. The arrangement of the data and of the discussions is clear and concise. One rather serious error must be noted. The authors state that Harrington and Barger have synthesized triiodo trihydroxy propionic acid, and that this substance is identical with thyroxine. Thyroxine synthesized by Harrington and Barger, is, of course, represented by the following formula

The *De Lamar Lectures** for 1926-27, which represent the sixth series, consist of eleven addresses delivered at the School of Hygiene and Public Health of the Johns Hopkins University. Professor F. Henfeld, director of the Robert Koch Institute for Infectious Diseases, Berlin, contributes a paper on natural immunity in its significance for epidemiology, illustrated by references to anthrax, typhoid, typhus, malaria, tuberculosis, and syphilis. The same author also deals with variability in bacteria, and shows that micro-organisms may, on the one hand, lose their virulence and viability, and on the other hand in exceptional cases, acquire new pathogenic properties. Dr. Alfred E. Cohn of the Hospital of the Rockefeller Institute for Medical Research, in his lecture on heart disease from the point of view of public health, shows that the problem of heart disease includes disability from infectious diseases such as rheumatic fever and syphilis and disability incident to the process of ageing. Professor G. H. F. Nuttall of Cambridge gives an interesting account of some pioneers in parasitology, including Alexander Kircher, Robert Boyle, Redi, Leeuwenhoek, Spallanzani,

Pasteur, Leuckart, Leidy, Giard, Koch, Manson, Laveran, Metchnikoff, Walter Reed, Loeffler, von Boetting, Ehrlich, David Bruce, Crassi, Ronald Ross, Theobald Smith, and Arthur Looss, illustrated by their portraits. The history of tularemia forms the subject of a lecture by Dr. Edward Francis of the United States Public Health Service, who gave the name to this disease on account of the presence in the blood of the causative organism, *Bacterium tularense*. Dr. William H. Park, director of the Bureau of Laboratories, New York City Department of Health, discusses the etiology and prevention of measles. While, like all other observers, he is convinced of the prophylactic value of convalescent serum, he is not satisfied as to the etiological connexion with measles of the organisms described by Tunnichiff, Fisher and Terry, or Dr. Cristina and Caronia. Professor A. R. Dochez of the College of Physicians and Surgeons, Columbia University, describes the preparation and use of scarlatinal antitoxin, the early administration of which either prevents the development of complications, or in certain cases at least lessens their severity.

Dr. WALDEMAR UNGER has contributed a useful handbook dealing with the psychoneuroses, functional neuroses, and exhaustion states* to the series of volumes on differential diagnosis which is appearing under the editorial direction of Professor HONIGSMANN of Giessen. In this well arranged and interesting book a comprehensive survey is given of neuroses, neurasthenias, psychasthenias, migraines, and epilepsy, this is followed by a simple practical account of the various methods of diagnosis. The differential diagnosis of the various conditions is lucidly described. Although in a volume of this size full details of so extensive a subject can hardly be expected, Dr. Unger certainly contrives to combine a wide outlook with many useful clinical hints. The book is indexed, and contains a short bibliography of German literature on the subject.

A ninth edition (which represents the fifty seventh printing) of *Gould's Pocket Medical Dictionary** has now appeared, and we learn from the preface that over 700,000 copies of this and the other two dictionaries compiled by Dr. GEORGE M. GOULD have already made their way into the bookshelves or overcoat pockets of medical practitioners and students. So far as we can judge, a wise selection has been made from the many new words which are coined every year by workers in medicine and the collateral sciences. It is no easy task to keep a small volume like this within reasonable bounds, and at the same time to do justice to an ever growing terminology. The care taken by Dr. Gould in choosing new words for inclusion and in defining them adequately will no doubt be repaid by a further lease of popularity for this useful little reference book.

* *Praktische Differentialdiagnostik*. Herausgegeben von Professor Dr. Georg Honigsmann. Band II. Neurologie. Teil II. Psychoneurosen. Funktionellen Neurosen, und Erschöpfungszustände. Von Dr. Waldemar Unger. Dresden und Leipzig: T. Steinkopff. 1927. (Med. 8vo pp. 165-300. 3 figures. R. 18.)

* *A Pocket Medical Dictionary giving the Pronunciation and Definition of the Principal Words used in Medicine and the Collateral Sciences*. By George M. Gould, A.M., M.D. Ninth edition, revised. London: H. K. Lewis and Co. Ltd., 1928. (Fcap. 8vo. 10s. net.)

PREPARATIONS AND APPLIANCES

A SYRINGE FOR INJECTING VARICOSE VEINS

VARIOUS improvements—the result of experience in the use of the earlier model—have been incorporated in the new type of syringe for the treatment of varicose veins devised by Drs. Katherine Cellan-Jones and C. J. Cellan-Jones and described in the *British Medical Journal* of May 5th (p. 763). The syringe

is now made in capacities of 3, 5, 10, and 20 cubic centimetres, and the length has been reduced by increasing the diameter of the barrel and using only one ampull in the capillary tube instead of two as previously. The syringe is obtainable from Adair Dutt and Co., 47 Victoria Street, S.W.1.

CALMITOL

* Calmitol dermal lotion (H. R. Napp, Ltd., 3 and 4, Clements Inn, Kingsway, W.C.2.) is an ether alcoholic solution of camphor aldehyde which also contains menthol and a very small amount of lysozone. It is recommended for the relief of itching in such conditions as eczema, pruritus, etc. It is stated to be a strong disinfectant. An ointment is also supplied.

* *Le Métabolisme Basal ses Applications en Clinique*. Par Claude Gautier et René Wolff. Collection des Actualités de Médecine Pratique. Paris: G. Doin et Cie. 1928. (8½ x 7 pp. vi + 172. 11 figures. 15 fr. net.)

* *De Lamar Lectures 1926-1927*. Baltimore: The Williams and Wilkins Company. London: Baillière, Tindall and Cox. 1928. (Roy. 8vo pp. 224. 22s. 6d. net.)

SILICOSIS ON THE WITWATERSRAND
GOLD MINES

[FROM OUR CORRESPONDENT IN PRETORIA]

MUCH the most important industrial disease in South Africa is the silicosis produced in extracting gold from the conglomerate of which both the pebbles and the matrix consist of quartz. This conglomerate, which contains over 90 per cent of free silica, is called blanket. During the first decade of the gold mining industry there was no compensation of miners contracting the disease, and the incidence was high. The medical commission on miners' phthisis in 1911 estimated the prevalence at 26 per cent, which probably represents the situation during the whole of the period 1902 to 1912, since there is no reason to suppose that any decline occurred during that time. Thereafter legislation for the compensation of sufferers and the elimination of siliceous dust was introduced, and the prevalence of the disease very rapidly diminished. The most important and obvious reason for this was the automatic removal of silicotic miners from underground work after compensation.

In 1916 a medical bureau was appointed by the State to examine all miners previous to employment and at intervals not exceeding six months throughout employment. Since then the prevalence of silicosis and the amount of the disease annually produced has been accurately ascertained. The figure for the year 1916-17 was about 8 per cent. A further notable drop occurred in 1920-21, when the number of cases among the 13,682 miners examined was found to be only 467, a prevalence of 3.4 per cent. This diminution was partly owing to a genuine fall in the production of cases as the result of improved conditions, and partly to the limitation of benefits imposed by the Act of 1919 on any miner who does not make a claim for an award within three months of being notified that he has silicosis. In 1922-23 only 425 cases were found among 12,691 miners examined.

Recent Increase in Prevalence

Since that date, however, there has been a steady rise in prevalence. In the year 1925-26 there were 621 cases among the 12,883 miners examined—that is, 4.8 per cent. This rise in "prevalence" is due to a definite rise in "production" of the disease, and is discussed by Dr L. G. Irvine, chairman of the Miners' Phthisis Medical Bureau, in the latest report upon the work of the Bureau, covering the two years ended July 31st, 1926. The delay in its preparation was due to the ill health of the former chairman, Dr W. Watkins-Pitchford, which ultimately resulted in his resignation and retirement in July, 1926. The present report, therefore, deals with the last two years that the work remained under the direction of Dr Watkins-Pitchford, and thus completes the record of the ten years during which it was carried out under his supervision.

Since 1917 it has been possible to ascertain the annual "production" of silicosis with reasonable accuracy. Dr Irvine estimates the annual average production from 1917 to 1920 at 4.2 per cent, from 1920 to 1923 at 2.1 per cent, and from 1923 to 1926 at 3.5 per cent. The rise during the last three years was steady, the figures being 2.8, 3.7, and 3.9 per cent respectively. This statistical increase in the production rate for silicosis certainly does not reflect any deterioration in the occupational and hygienic conditions which produce the disease; these conditions have progressively improved since compensation was first introduced. The most important factor determining the production rate in any group of miners is the duration of time during which the members of the group have been exposed to underground conditions. Other things being equal, the liability of any miner to contract silicosis depends directly upon the number of years he has spent in underground work. Consequently the incidence of silicosis amongst any group of miners will also be in a direct relation to the number of years which the individuals composing that body have worked underground. It has been shown¹ that the proportion of new cases of silicosis among "long-service miners"—that is, those who have worked for more than

six years underground—was very much greater than among the "short-service miners"—those who have worked for not more than six years underground. Further, it was shown that the proportion of "long service miners" has steadily increased since 1918. The average number of years worked by the individuals composing the "long service" group is also increasing. The extent of the increase in recent years of cases of compensatable silicosis which cannot be accounted for by such an analysis into short and long service groups is explained by increased refinement of the Bureau's standard of selection of cases.

Improvement in Diagnostic Methods

From the outset of its work the Bureau has relied in making a diagnosis upon (1) clinical examination, (2) radiographic examination of all cases, being able not only to compare the radiographs of very large numbers of individuals with the results of their clinical examination, but also to obtain a systematic series of successive radiographs taken at regular intervals in each case, both prior and subsequent to the development of signs of silicosis, and (3) pathological examination of the lungs of deceased miners, the results of which are compared with the evidence derived from clinical and radiographic examination of the same individual, made during life. The correlation of data derived from these three sources has become increasingly exact with each advance in radiographic technique. Definite improvements in the already high technical quality of the radiographs resulted in 1924 in a fresh systematic investigation with the object of obtaining on even more exact correlation between the conditions found *post mortem* in the lungs of deceased miners and the radiographic appearances shown in negatives taken from the chests of the same individuals shortly before death. The different types of radiographic appearance which are found in normal and abnormal chests have been carefully standardized. Definite criteria of the pathological appearances found in the lungs after death have also been determined, so that the pathologists are able to make a definite and consistent report in each case regarding the presence or absence of silicosis, and of the different degrees of that disease. The results of this investigation during the past two years have enabled the Bureau to refine further its standard of diagnosis of "the earliest detectable specific signs," known legally as the "ante primum" stage of silicosis. This stage, which is compensatable, is deemed, according to the Miners' Phthisis Acts Consolidation Act of 1925, to be present, whether or not capacity for work is impaired.

Effect of Initial Examination on Silicosis Incidence

Since 1916 all persons who desire to enter for the first time upon underground work in a scheduled mine as full time miners have to submit to an initial examination. The great majority of these recruits have not been engaged in mining work elsewhere. Such mining recruits who have not previously been exposed to underground conditions are referred to as "New Rand miners." This is an interesting group to follow, since its members have not only not previously been exposed to silicosis-producing conditions, but they have been carefully selected as being specially unlikely to develop tuberculosis or silicosis as the result of exposure to underground conditions. The examination is necessarily a very strict one. Of the 6,126 candidates who presented themselves for the initial examination in the year 1925-26, only 32.84 per cent passed, 31.03 per cent being permanently, and 36.12 per cent temporarily, rejected. The great value of this examination is indicated by the fact that of all the "New Rand miners" who commenced work since 1916 only ten had up to the end of July, 1926, become the subjects of simple silicosis. The low incidence among this group is brought out strikingly when they are compared with the "Old Rand miners"—that is, those who have worked only on scheduled mines, but commenced work prior to August, 1916—and even more when compared with the "Miners, Rand and elsewhere"—that is, those who have worked in scheduled mines and also in other mines, either in South Africa or overseas. On comparing the returns for these three classes the incidence for silicosis is found to be much lower for each year of service among the "New Rand miners" than among the "Old

¹ See regarding "Contributions to the Study of Silicosis" Publication of the South African Institute for Medical Research No. 19, 1926.

Rand miners," and very much lower than among those miners who had worked on the "Rand and elsewhere." These facts appear clearly in a table showing the number of cases of silicosis detected at periodical examinations among working miners during the two years 1924-25 and 1925-26. It reveals that while the incidence of simple silicosis among the "New Rand miners" who had worked for any period not exceeding six years was nil, the incidence among "Old Rand miners" was 0.88 per cent, and among the "Miners, Rand and elsewhere" 2.51 per cent. Among the miners working in their seventh, eighth, and ninth years the incidence in the three classes was 0.44, 3.73, and 8.33 per cent respectively. This result was, of course, to be expected, for not only have the "New Rand miners" had to survive the stringent initial examination of the Bureau, but they were never exposed to the hygienically unsatisfactory conditions which obtained in the early days of mining on the Rand.

Native Labourers

Some 180,000 natives are employed on the Witwatersrand mines, but only 400 of these are technically miners, the remainder doing the unskilled labouring. The few native miners are usually included for statistical purposes among the native labourers. The Miners' Phtisis Acts Consolidation Act of 1925 made the medical service for natives on the mines a whole-time service, subject to a power of exemption in the Minister under special circumstances. This has effected an extensive change in the service. Previous to the coming into force of the Act the service consisted of fourteen whole-time and twenty-two part-time medical officers. On July 31st, 1926, it comprised thirty-one whole-time and only eight part-time officers. This transformation is making for greater uniformity of procedure and generally for all round efficiency.

The native labourers are submitted to "initial," "periodical," and "final" medical examinations. These examinations are conducted by the mine medical officers in their capacity of "examiners" under the 1925 Act, the Bureau exercising a general supervision and control over this work mainly by means of periodical visits of inspection. That the amount of work entailed by these examinations is tremendous will be appreciated when it is realized that the total complement of labourers is replaced, on the average, to the extent of approximately 90 per cent during each year. The native recruits before commencing work on the mine undergo in most cases three medical examinations. At the time of recruitment in the native territories they are subjected to a preliminary medical examination for fitness at the recruiting centres in these territories. On arrival at Johannesburg they undergo, at the Central Hospital of the Witwatersrand Native Labour Association, the official "initial" examination, a stethoscopic examination conducted by the medical staff, which consists of six examiners. During the year 1926-27, of the 160,000 initial examinees slightly over 5 per cent were rejected. On being drafted to the individual mines they are again stethoscopically examined and weighed by the mine medical officers who may further reject any they consider unfit. The "periodical" examination, which is made at intervals not exceeding three months, consists primarily in weighing each native. If he is found to have lost 5 lb or more in weight between two consecutive weighings, or 6 lb or more between three such weighings, he is set aside for individual stethoscopic examination by the mine medical officer. That these figures are suitable has been demonstrated by special investigation, which showed that in 65 per cent of bacteriologically verified cases of simple tuberculosis in mine natives there is a loss of weight of these amounts at the periodical examinations. In addition, the regulations require that any native who on inspection appears to be in ill health shall be reserved for special stethoscopic examination. The medical examiner is responsible for the proper conduct of both the weighing and the inspection.

An investigation by the Bureau in 1924 showed that there existed some 5 per cent of undetected cases of tuberculosis with silicosis among long service natives—that is, labourers who have worked upon any one mine for five years or more. A three-monthly stethoscopic examination

of these long service natives was therefore introduced by regulation under the 1925 Act. The Chamber of Mines has supplemented this statutory examination by an annual radiographic examination. It is hoped that these various examinations will assist greatly in the effort to eliminate from underground workings all native carriers of tuberculosis. Silicosis is not infrequently discovered at the initial examination. This is explained by the fact that a considerable proportion of all the natives employed have previously worked in the mines.

Natives found by the examiners to have indications of silicosis or tuberculosis are sent for confirmatory examination to the Bureau. Of the average number of 178,000 natives employed on the scheduled mines during the year 1925-26 and of whom the average number of 133,260 were employed underground, simple tuberculosis was found to be present in 566, simple silicosis in 231, tuberculosis with silicosis in 446. The prevalence rate per 100,000 of all native labourers was for silicosis in all forms 380, and for tuberculosis in all forms 568. Whereas the immense majority of cases of compensatable disease among European miners have always been cases of simple silicosis, among native labourers the great majority have been cases of tuberculosis, mostly without silicosis. As compared with the European miners the incidence of simple silicosis among native labourers is low, a phenomenon which appears to be mainly due to the migratory habits of the latter silicosis, which takes time to develop, is much less likely to occur among them.

ROYAL COMMISSION ON LOCAL GOVERNMENT

EVIDENCE ON BEHALF OF THE MINISTRY OF HEALTH

THE evidence of Sir W. Arthur Robinson, K.C.B., Secretary of the Ministry of Health, given before the Royal Commission on Local Government, has just been published. Most of the previous evidence has had only an indirect medical interest, but Sir Arthur Robinson dealt with the need for accelerated progress towards whole-time appointments of medical officers of health, as well as with the distribution of health functions between local authorities. His statements and suggestions therefore, call for the special attention of the profession. This was Sir Arthur Robinson's second appearance at the witness table, his earlier evidence was directed to showing in what respects the existing organization of local government appeared to the Ministry to be defective, and on what principles improvement might be secured. In the Minister's view the most important question before the Commission is a reduction in the number of existing local authorities, with an extension of local areas of government, which will make possible economies in administration. The second part of his evidence was consequent upon evidence since submitted by bodies representing county councils, municipal corporations and urban and rural district authorities.

Progress towards Whole-time Appointments of Medical Officers

Sir Arthur Robinson stated that the general effect of the evidence given by those entitled to speak for groups of local authorities appeared to be that the employment of whole time—as distinct from part-time—medical officers of health was desirable in all areas, and should be practicable in almost all areas when an effective reorganization of county districts had taken place, but that the rate of progress during the last fifty-five years towards a general system of whole-time appointments had been undefensibly slow. In 1873 the proportion of whole-time to total appointments in England and Wales was about one-fourth, it was now slightly more than one-third. While local authorities of all types agreed that whole-time appointments should be encouraged, some of them objected to being compelled in any circumstances to make such appointments, especially if they had to share the services of the medical officer with the county council.

The Minister recognized, Sir Arthur Robinson continued, that it was impracticable to institute immediate general compulsion to make whole-time appointments of medical officers of health and even after the reorganization of county districts, which is contemplated in forthcoming legislation, regular means

would still be needed to remove some of the obstacles to those appointments which county district councils have failed to surmount in the past. The Minister's suggestion, therefore, is that statutory provision should be made so that on a vacancy in any post held by a medical officer of health also engaged in private practice, it should be the duty of the county council, after consultation with every district council affected, to make suitable arrangements for the appointment of a medical officer of health by the county district council in whose area the vacancy had occurred. These arrangements should preclude the medical officer of health appointed from engaging in private practice, but it would be open to the Minister to decide, on representations being made to him, that, owing to the special circumstances of a particular locality, it was unreasonable, for the time being, to attach such a condition to the appointment.

In reply to the Earl of Onslow, the Chairman of the Commission, Sir Arthur Robinson pointed out that the real question would always arise upon vacancies. He insisted that the only way of getting accelerated progress towards whole time appointments was by securing that these vacancies, as they occurred, should be brought into the scheme for whole time appointments. The matter had to be picked up on each vacancy. On a vacancy occurring no permanent arrangements should be made until it could be filled as part of the duties of a whole time officer. To the Chairman's suggestion that whenever there was a vacancy a whole time medical officer of health should be appointed unless there was good reason to the contrary, Sir Arthur Robinson said that he would go further than that, whenever there was a vacancy nothing should be done to compromise the principle that there should be a whole time officer in that area, whether in combination with the county medical service or with other areas. He stated:

You see what happens now. You get one county district where the doctor leaves or where he dies or something of that sort. Now as it stands they can bring quite a good case. They can say 'Our area is not big enough to carry a whole time man. We have Dr So-and-so. He is a very good man indeed and we want to appoint him. We do not like the county medical officer of health and we do not like the county service. We have to do something, therefore we want to appoint Dr X who is a part-time man.' That happens over and over again."

The witness agreed with the Chairman's suggestion that what it came to was that a part-time medical officer of health was to be a locum tenens, and that directly arrangements could be made to appoint a whole time officer then the part-time officer should have no grievance in being turned out. The witness was ready to admit the utmost latitude, Dr X might be taken on for a year, or whatever the term might be, but gradually, as vacancies arose and the thing got organized there would be a whole time service throughout the country. He agreed that if a reorganization of districts came about as a result of the Commission's report a number of vacancies would automatically be created which would furnish an opportunity of dealing with the question much more extensively than in the past.

Sir Seymour Williams, a member of the Commission, said that he knew there was a general view in favour of the whole time officer, but he thought there was a contrary opinion among medical men themselves. Sir Arthur Robinson replied that he had never come across it himself. Lord Strachie, another member, then raised the question of comparative cost, which, the witness said, would depend on the size of the combined areas, the number of districts, and the sort of scale of salary. The examination of the witness by Lord Strachie then proceeded.

"I suppose, too it might depend on whether the British Medical Association come in and fix the standard as they wish to do for county council appointments?—They have never come in and wanted to impose a standard. They have never done that."

"Do you not think that it might be rather different under your proposals?—I do not think so. I think that what would happen would be that there would be discussions about the sort of pay these people ought to have, very much in the same way as we discussed the sort of pay that doctors ought to have under the National Health Insurance Act. I think it would not alter the situation at all the situation would be just the same as it is now. The fact that you have more whole-time officers does not alter the relation that you may have now with the British Medical Association."

"Of course that does not apply to part-time officers at all?—No."

"When you change your part-time officers to whole-time officers may not the same difficulty come in which happens now?—In so far as the British Medical Association concern themselves with the salaries of whole time officers now they would have more chances of doing it if there were more whole time officers but that would not increase the difficulty except in the sense that there would be more cases to deal with."

"I take it that you think they would probably come in and interfere?—They come in now."

"I know but under the new scheme?—Yes now and under the new scheme."

"Therefore probably it would mean increased cost?—No not necessarily. I think that is wrong."

Sir Seymour Williams suggested that a complete system of whole time medical officers of health must result in very considerable additional expenditure. He instanced the case of a part-time officer of two or three adjoining districts. The salary paid would not come to anything like the salary which it would be necessary to pay to a whole time man. Sir Arthur Robinson agreed that such cases would occur, but added that the present situation was that many of the district councils were paying an insufficient fee to a part-time officer, and, that being so, there would be an increase.

Distribution of Health Functions

The remainder of Sir Arthur Robinson's evidence was concerned with the rational distribution of functions between local authorities. He first pointed out the anomalies which at present occurred, whereby different functions were assigned in no consistent way to local authorities of different types. The first principle stated by the County Councils Association was that for certain purposes counties were the best areas of administration, the Minister's opinion was that there would be no advantage in giving statutory effect to such a principle because that action in itself would secure no advance towards agreement on the particular local government functions under discussion. Sir Arthur Robinson agreed, however, that for certain purposes counties were the best areas of administration—for example, when it was a question of managing institutions, such as tuberculosis sanatoriums or infectious diseases hospitals. The same consideration applied to some extent to the maternity and child welfare service, though this service was only in part institutional, and therefore here there was some difficulty in assignment.

The Minister's suggestions to the Commission, following upon the evidence already given, were that the school medical service should remain in the hands of the local education authority as already determined by the Education Act, and that the maternity and child welfare service should be dealt with by the authorities which administer the school medical service. At present there are 159 maternity and child welfare authorities which are not school medical authorities, and 26 school medical authorities, outside London, which are not maternity and child welfare authorities. It is also proposed to assign responsibility for the administration of Notification of Births Act and of the maternity and child welfare work to the same local authority in every area. It has been represented in other evidence to the Commission that the supervision of midwives should be made the responsibility of the same local authority in each area as that which controls the school medical service and the maternity and child welfare work, but certain restrictions upon the application of this view must, in the Minister's opinion, follow from the characteristics of the existing local education authorities, some of which have too small populations under their jurisdiction and too limited financial resources to be made responsible for providing a separate establishment and staff for the supervision of midwives. The suggestion of the Minister accordingly is that there should be statutory provision to enable urban authorities to which functions have been delegated under the Nursing Homes Registration Act to represent to the Minister that it is desirable that they should also be constituted into local supervisory authorities under the Midwives Acts. Notifications with respect to ophthalmia neonatorum, it is suggested, should be sent to the local authority providing treatment for the disease, whether or not that authority is the one which has the supervision of midwives.

As to the provision and maintenance of infectious diseases hospitals, this should be concentrated, in the Minister's opinion in the hands of county councils, and existing hospitals of this kind for which local authorities of other types are at present responsible should be transferred to county councils on equal terms. Sir Arthur Robinson pointed out to the Commission that there was in the country a serious shortage of accommodation for infectious diseases, including small pox—"roughly a 10 per cent shortage. That is too much in providing against infectious diseases, you may have an epidemic any day. The right way of meeting the danger was for the county councils to survey their own counties, find out where the shortage was, and prepare a county scheme. Whether, having got the scheme, the county council took over any existing hospital run by a combination of authorities, or left that hospital to be run by those authorities in connexion with and as part of the county scheme, was a detail. What he wanted was to ensure that the provision was made in other words, he would lay the duty upon the county council of providing this accommodation, but would allow it to do so in collaboration with other authorities if it thought fit."

We publish in the *Supplement* this week, on page 142, a further memorandum of evidence, dealing particularly with whole-time public health appointments, submitted to the Royal Commission by the British Medical Association.

British Medical Journal.

THE BACTERIAL FLORA OF THE INTESTINES

ONE of the most useful functions of a sectional session during the Annual Meeting of the British Medical Association is the open debate by experts of a question which, though of everyday interest to all medical men and women, needs some specialized training for its intimate understanding. This function the Section of Pathology and Bacteriology at Cardiff exercised very profitably by encouraging discussion on the influence of the bacterial flora of the intestine in health and in chronic disease. That an unrestrained airing of opinion was desirable on this matter is shown by recurring claims to the successful detection among the host of intestinal bacteria of the cause of some human disease and to the curing of acute and chronic ailments by administration of a vaccine prepared from faecal micro organisms. Three instances of therapeutical practices based on inadequate criteria of bacterial pathogenicity were cited by Sir Thomas Horder—namely, the employment of vaccines containing the late lactose fermenting bacilli the so called serum resisting *B. coli*, and streptococci incriminated only because they were present in excess of the normal. Later in the discussion, however, Sir Thomas Houston joined issue with these sweeping criticisms, and put in a word for the enterococci as being probably pathogenic.

In no branch of bacteriology are common sense and experience more essential than in the study of the bacterial flora of the intestine. Common sense is needed in order to keep continually in mind the fact (or some would say the paradox) that the microbes within the lumen of the large intestine are nevertheless outside the body, separated from the deeper tissues by what Professor Cruickshank has called the impenetrable barrier of the intact mucous membrane. Experience is needed because of the great complexity of the intestinal flora. Most of the microbes within the intestines are useful scavengers and their numbers and variety depend on the diet and habits of their host. Then distribution in the intestinal canal may, moreover, be determined by a disturbance of digestive function—by the presence, for example, of achlorhydria—a fact which bears considerably on the alleged etiological relationship between an abnormal distribution of *B. coli*, enterococcus, and *B. welchii*, and cases of pernicious anaemia. Therefore, no opinion on the relative proportions of different groups of bacteria is of any value unless it takes into account the condition of the intestinal tract and the diet of the subject investigated. As examples of the effect of diet on the intestinal inhabitants may be mentioned the relative simplicity of the bacterial content of an infant's stool when breast milk is the only food, and the rapid change to a more variegated flora on artificial feeding or weaning. In like manner simplification of the bacterial flora to microbes of the aciduric group can be brought about by adding lactose or dextrin to the diet. A corresponding phenomenon may be found in the large excess of streptococci in the lower bowel

often observed after rapid emptying of the intestine by a saline purge. The work of Cramer, Mottam, McCollum, and others suggests, moreover, a close relation between diet and alimentary toxæmia: a diet deficient in vitamin A appearing to break down the barrier of the intact mucous membrane, possibly (as suggested by Cramer) by altering the permeability of the mucous cells.

As will have been seen from the report published in the *British Medical Journal* of August 11th (p. 252), nearly all the speakers who took part in the discussion at Cardiff two months ago were in general agreement with the views expressed by Professor Cruickshank in his opening paper, of which the text appears in our present issue at page 555, but it is curious that little if any mention was made of the value of the test diet before bacteriological examination of the faeces or of the importance of examinations for blood and pus. The conclusion that seems to be justified from this discussion is that the importance of the bacterial flora of the intestines in relation to health and disease has been exaggerated in the past, and that the attention paid in recent years to alimentary toxæmia is now on the wane. This attention fulfilled its function by provoking a considerable amount of work, some of abiding value, but it also created hopes that have not been fully realized. The present decline in the administration of alleged intestinal antiseptics may be regarded as an instance of the tempering of enthusiasm by knowledge and experience. At the moment all the clinical and laboratory experts are, however, by no means agreed in regard to the importance of intestinal micro organisms. It is possible, indeed, that a joint discussion of this topic by the Sections of Medicine and of Pathology and Bacteriology would have been attended with a little liveliness.

In the meanwhile signs are not wanting that hence forward the direction of progress is likely to be towards a better understanding of the effects of diet on intestinal disease rather than a continuation of the search for individual pathogenic bacteria among the intestinal contents. The value of a dietary rich in lactose in the treatment of typhoid fever, the efficacy of lactose and dextrin in some types of constipation, and the possibility that changes in the permeability of the intestinal wall may be caused by vitamin deficiency, are indications of the future usefulness of intestinal bacteriology in practical medicine.

LIMITATIONS OF MEDICAL BENEFIT

TWO recent letters in the *Times* from Dr. Graham Little, M.P., with the correspondence to which the earlier letter gave rise, deserve some attention, lest the confusion of erroneous detail and deduction that encumbered the first letter should obscure the real and more important points which seem to have been in Dr. Little's mind and on which there is substantial agreement among those members of the medical profession who are concerned with national health insurance practice and administration. These relate to the limitations or restrictions of medical benefit, and are two in number. One of them is the real limitation of medical advice and treatment of insured persons to that which can properly be given them by general practitioners as a class. This is not, however, a narrow service, as Dr. Little (who does not seem to be very familiar with the work of general practitioners) would appear to think, it is a very wide service, and requires and receives a high degree of knowledge

and skill. With fuller knowledge he would have refrained also from suggesting that insurance practitioners give this service reluctantly and grudgingly, with a desire to escape from the whole business at the earliest opportunity. The attempts made from time to time on their behalf, usually with success, to alter and improve certain of the arrangements or regulations of the insurance scheme and to secure a satisfactory remuneration are no proof at all of any such general attitude. Nevertheless, it is true that medical benefit is seriously restricted and rendered less beneficial to its recipients than it might be, by reason of the fact that no consultant and specialist services and no pathological laboratory facilities are provided within the scheme. Such provision is desired and has long been urged by the medical profession. It was declared by the recent Royal Commission on National Health Insurance to be the most immediate need, and its cost to be relatively small. The Ministry of Health was anxious to pass legislation to make this provision. Nothing but the opposition and obstruction of the approved societies themselves has prevented it from being in existence to day. The need for the creation of a public opinion which will enable this opposition to be overcome is evident, and it is to be hoped that Dr Little will lend his valuable aid to this end.

The other limitation referred to is rather an apprehended than a real one. The financial arrangements lately made with the retail pharmacists do not in fact in any way restrict the liberty of an insurance practitioner in prescribing whatever he thinks it necessary for his patient to have, but the fear is lest they should have a tendency in that direction. The arrangement is that the pharmacists take the whole of the residue of the medical benefit fund after all other claims upon it have been satisfied, and in return for this total sum undertake to supply insured persons with whatever is properly proscribed by insurance practitioners. This was only suggested by the Ministry of Health in an emergency from which no other means of escape was apparent, but such an arrangement has obviously undesirable features. The Conference of Panel Committees has declared that it is 'against public policy', and it is clear that it may put temptation to improper economy in the way of pharmacists themselves and may at least induce them to try to bring undue pressure on Insurance Committees or insurance practitioners. There is no evidence at present that this has been done, though individual Insurance Committees, both before and since this arrangement was entered into, may have acted unwisely with reference to particular pharmaceutical preparations. There has from the beginning of national health insurance been provision for dealing with any wantonly extravagant prescribing on the part of medical practitioners, but this provision has not been altered in any material way in consequence of the new arrangement with the pharmacists. So long as this reasonable liberty of practitioners to order what they think necessary is maintained the bargain with the chemists is not directly their concern, but there is every reason why Dr Little and other members of Parliament should keep a watchful eye upon the working of a dangerous and undesirable agreement.

The remedy for limitations of medical benefit such as these is not the abolition of the national health insurance scheme, which has been approved in principle by public opinion and by both the great representative conferences of the medical profession. The remedy is rather the removal of the limitations and the extension of the scheme. Nor do they call

for inquiry by a Royal Commission, such as Dr Graham Little appears to think necessary, every three or four years. The need is rather for the carrying into early effect of the more important recommendations made by the Royal Commission which reported only two years ago.

THE LEAGUE OF NATIONS AND THE DRUG TRAFFIC.

THE traffic in opium and other dangerous drugs (writes our correspondent at Geneva) has taken a larger place than usual in the proceedings of the League Assembly. The report on this subject was made by Dr Witold Chodzko, director of the State school of hygiene at Warsaw and former Minister of Health for Poland, who said that the manufacture of harmful drugs continues to be greatly in excess of legitimate requirements, and new methods of manufacture are rendering the supervision of the international traffic increasingly difficult. With regard to the situation in China, Dr Chodzko congratulated the British Government on its decision to withdraw its protection and withhold the right to fly the British flag from any vessel proved to have been engaged in smuggling in navigable Chinese waterways. He went on to say that the Advisory Committee on Opium had been very much concerned at the efforts of certain manufacturers to find substitutes for morphine since this alkaloid was made subject to control. One substitute is benzoyl-morphine, already manufactured in comparatively large quantities, which has been shown to possess all the properties of a drug of addiction. Moreover, the morphine content in benzoyl-morphine can readily be recovered, and hence quantities of morphine which escape supervision can be placed on the market, in addition to this there is a whole series of other morphine esters having the same properties. The attention of the Council of the League is being drawn to the necessity of placing benzoyl morphine, and possibly other substances, under control forthwith. Twenty-seven Governments have accepted the principle that eucodal and diacode should be included among drugs coming under the 1925 convention, but the efforts of a number of the signatory countries are said to be intermittent and wanting in vigour. It was noted with satisfaction that the Spanish Government has decided to institute a monopoly system for the trade in drugs. A further scheme for the limitation of the manufacture of drugs has been transmitted by the United States Government to the League of Nations, and will be examined by the Advisory Committee on Traffic in Opium at its next session. The debates in the Assembly on this subject were chiefly noteworthy for the protestations of Eastern delegates. The Japanese delegate declared that his own country was not an opium producer, its annual output was only 3,000 kilograms, all of which was used by the Government for medicinal purposes and none exported. The Siamese delegate similarly protested that his was not an opium-producing country, it was even obliged to import opium from India, and the Government had established a monopoly for drug imports. The Indian delegate thought that his country's sacrifices for the suppression of the opium traffic had not been recognized, the Indian Government had always made opium a monopoly, both as to cultivation and sales. It had steadily followed a policy of reducing the area under poppy, and the total loss of revenue it had sustained amounted to something like 72 million pounds in eighteen years. The licensing system had been at work since 1923, and care was taken to see that all exported opium reached its proper destination.

* As announced in the *Journal* of August 25th (p. 351). Part III of the Dangerous Drugs Act 1920 which provides for the control of morphine, heroin, and cocaine has been applied by Order in Council to benzoyl morphine, dihydro-oxycodone (eucodal), dihydro-codone (diacode), and their respective salts and to any preparation admixture and extract containing them.

exports for Persia and Macao were already prohibited, and no exports of opium from India would be allowed after 1934. Finally, the Persian delegate declared that as great sacrifices had been made by his own country, much had been said about India, but opium amounted to only 1 per cent of India's total exports, and to 20 per cent of Persia's, so that Persia's efforts to cut down the traffic were correspondingly virtuous. His country, he said, had fulfilled all the obligations to which it had subscribed, and had just passed a law making opium a State monopoly. So all the Governments are arrived in white robes, and yet, says Dr Chodzko, the situation is extremely serious, if not alarming. A proposal was made to the Assembly by Dame Edith Lattelton, on behalf of Great Britain, to appoint a commission of three independent persons to inquire into and report on the situation as regards opium smoking in the Far East. It is intended that the commission shall visit the Straits Settlements, Java, Siam, Hong-Kong, Japan, and possibly Korea, China, and Burma. The British lady delegate, in urging her proposal, said that there was in existence a large illicit traffic in opium in the Far East which nullified the efforts of all the Governments concerned to control and restrict consumption, the difficulties were illustrated by the case of Hong Kong, where the Government of the colony estimated the consumption of illicit opium to be many times that of Government monopoly opium. The commission would report on the actual position at the present time in regard to control, the difficulties encountered, and the possible means of remedying them. The principle of the proposal met with general acceptance, except from the Chinese delegate, who said that while there had been a recrudescence of poppy cultivation in China, the Chinese Government was far more seriously perturbed by the organized smuggling of opium derivatives and cocaine from European countries. He contended that the field of investigation should not be limited to the countries of the Far East, but should include all countries which produced or manufactured opium and other dangerous drugs. Opposition to the British proposal was forthcoming, however, on the ground of expense, and the proposal, like other proposals initiated or supported by Great Britain, has had to run the gauntlet of the Finance Committee of the League, which this year has ground the League budget "exceedingly small." Not the least resolute economist of all has been the British representative on the Finance Committee. With regard to the proposal for an opium inquiry, this was finally placed upon a less expensive basis, and the League Budget Committee eventually agreed to grant £4,000 towards the cost. It is expected that this will exceed £8,000 the British Government has offered to contribute £2,000, and other States whose territories the inquiry will cover will be asked to contribute the balance. Among the delegates who voted against the proposal in the Budget Committee were those of Italy, Portugal, China, and Japan.

INFANT MORTALITY AND WELFARE WORK.

WHENEVER a reduction in the mortality rate of a disease follows some specific effort, it is always open to someone to assert that the disease was changing in its character and becoming less virulent, and that the reduction in mortality would have taken place in any case or could have been produced by other means. This argument is not easy to apply to the reduction in infant mortality rates, because there is more than one disease concerned, and in any case nobody will assert that infantile disorders when they occur are much milder in character than they used to be before infant welfare work became such a prominent feature in the public health programme. It may be said that no one wishes to deny the value of welfare work, but it must be remembered that there is a certain body of opinion which views with suspicion the inter-

ference of public authorities in the private health of the individual citizen and his children. It is necessary, therefore, that the value of welfare work should be firmly established upon a sound scientific basis so that there is no argument left on the score of its not being necessary for the health of a nation. Such a basis will be found in Dr R. M. Woodbury's book *Infant Mortality and its Causes*,¹ and in particular the chapter on infant mortality and preventive work in New Zealand. It is well known that the infant mortality rate for the white population in New Zealand was in 1924 the lowest for any country in the world—namely, 40.2. Dr Woodbury analyses the position on a strict statistical basis, and he shows beyond any shadow of doubt that the progress in infant welfare work in that Dominion is directly responsible for the remarkable position which New Zealand has won in her control of infant mortality. The different types of work concerned under this general term of "infant welfare" also receive attention. Beyond the welfare clinics the good results have also to be in part attributed to such influences as the establishment of State maternity hospitals, the registration of births, the newspaper health articles, and the work of infant life protection, which comprises supervision of babies boarded out apart from their mothers. The part played by these various activities has recently been analysed for a neighbouring region of the world, and in the Health Bulletin of the State of Victoria, Australia, Dr Vera Scudlbury deals especially with early notification of births and the importance of natural feeding. In the last decade there has been a very rapid growth in Victoria, as elsewhere, in infant welfare work, both in the towns and more importantly in the rural areas the latter being aided by an infant welfare section on the "Better Farming Train" run by the railway and agricultural departments during the past three years.

-NOISE AND NEURASTHENIA

IN a paper read to the recent conference on welfare in industry at Oxford, and published in the September issue of *Industrial Welfare* Dr Vilhjálmur Culpin makes the point that, while certain influences, such as overwork and noise, are often cited as causes of neurasthenia, this condition is more correctly to be ascribed to the reaction of the patient. Such unpleasant things as noise are, in short, convenient pegs on which the nervous subject hangs his symptoms, the problem is one of personal adjustment, and will not be solved by removing the alleged cause. Dr Culpin remarks that he can find no evidence that noise causes nervous breakdown, those who complain about it present other nervous symptoms, the emotionally stable man can adjust to noise very quickly. To some highly strung people (and, we would add, to the over-fatigued) some noises are very distressing, but this, while admittedly a sound argument for diminishing noise, is not necessarily evidence that nervous breakdown can be directly caused thereby. Dr Culpin adds that there is no proof that occupations in which there is noise, overwork, or monotony show a higher nervous sick rate than others, indeed, there is, he says, at least some evidence in the contrary direction. But noise by day and noise by night seem to us two different things. A man who has learnt to disregard the roar of day-time traffic or to ply his job without discomfort amidst the din of a workshop may suffer acutely from intermittent assaults upon his ears in the night hours—sudden fierce sleep-destroying noises against a background of comparative silence. The hardened evolutionist may view without regret the gradual elimination of the nervously unfit by

² No. 13, January-March 1928.

electric motor horns, open exhausts, rattling lorries, and pneumatic drills but the practising doctor will continue to look upon noise as an evil, and will support any measures to mitigate the pandemonium which engineers have let loose upon us. Thus while agreeing with Dr. Culpin that too much emphasis is still laid on environment and too little on personal reaction to it we shall continue to hope for less stimulation of the auditory centres along our uphill path to Utopia.

NOTIFICATION OF MENTALLY DEFICIENT CHILDREN

THE Board of Education has now issued its new Mental Deficiency (Notification of Children) Regulations, the draft regulations a summary of which appeared in the *Journal* of August 4th (p. 220) having been published for the required period, and having been confirmed by the Board with a slight amendment. These regulations were necessitated by the recently passed Mental Deficiency Act, 1927, and merely carry out the amendments made therein of the original Act of 1913, so far as the work of the Board of Education is concerned. These amendments provide that mentally defective children in all appropriate cases may now be dealt with in any one of three ways—by being placed under supervision or guardianship, or sent to an institution—whereas under the original Act those cases in which the Board of Education certified that there were special circumstances could be dealt with in the first two of these ways only, and those who shortly before leaving a special school or class were notified by the local education authority to the local mental deficiency authority could be dealt with only in the last two of these ways. These changes are of great practical importance, the latter should result in the notification of all children leaving a special school or class (provided that the diagnosis of mental deficiency in the technical sense has been correct), though the degree of supervision found to be necessary will of course, vary considerably in different cases. The change in the definition of the classes of mentally defective persons made by the amending Act is naturally also of great importance in this connexion, though it does not of itself necessitate any alteration of the notification regulations of the Board of Education. With the regulations and the accompanying memorandum (Circular 1399) is issued a revised "Form of Report on Child Examined for Mental Deficiency" (Form 306 M), but, apart from slight modification of the heading, this form does not differ from the old one. It may be pointed out that the power of a local education authority to certify "special circumstances" in particular cases is a very valuable one, and may well be interpreted more widely and used more frequently than has sometimes been the custom.

LAENNEC

DR. GERALD B. WEBB of Colorado Springs has done well to reprint with additions his article on René Théophile Hyacinthe Laennec from last year's volume of the *Annals of Medical History*. In the preface he quotes a warmly enthusiastic appreciation of Laennec's work and originality from Thomas Addison of Guy's Hospital, who was his junior by a dozen years. The origin of the name Laennec is doubtful, and may be either "lenn" a reader, or "laen" a pond or lake, and according to W. S. Thayer was pronounced Lennec. History does not record any hints of juvenile precocity, and he lived the wholesome open-air life of a boy interested in natural history. When little more than 14½ years old he began to study medicine at Nantes, and five years later went to work at the Charité in Paris under Corvisart, whose alertness and keenness attracted though his brusqueness and sarcasm

repelled him, and led to his collecting and subsequently publishing his teacher's aphorisms. In 1802 Laennec's first published article, on ossification of the mitral valve, appeared, and he became an active morbid anatomist, writing much on the abdominal viscera, while having a hard struggle to get a living. The story of his quarrel with Dupuytren, "the greatest of surgeons but the least of men," is well told, and then his gradual rise to practice is unfolded. Laennec apparently had many ailments to contend with—asthma and headaches when a student, cholera at the age of 27, gout when 33, angina pectoris both before and after the gout, and finally pulmonary tuberculosis which carried him off at the early age of 45 years. Dr. Webb describes the invention of the stethoscope, the publication of the *Traité de l'auscultation médiate* (first edition 1819, second edition 1823), and illustrates his attractively written memoir with thirteen full page plates. Our readers will recall that the centenary of Laennec's death was commemorated in Paris eighteen months ago and that this country was fully represented at the official celebrations organized by the Académie de Médecine.²

CONVALESCENT CARE IN GREAT BRITAIN

A REFERENCE to the importance attached to the provision of facilities for convalescent treatment in Britain, made in a review of *Convalescence: Historical and Practical* by Dr. John Bryant of Boston, Mass. (August 11th, p. 265), has been taken to suggest that the existing state of affairs in this country can be regarded as entirely satisfactory. While it appears that provision for convalescence is generally more extensive than in the United States—as described by Dr. Bryant—there are certain areas where a number of the leading hospitals have neither a convalescent home nor a convalescent fund as an integral part of their organization. In many cases, however, their almoners are charged with the arrangement of convalescent care, and facilities for this are obtainable through homes which, although not owned or controlled by the hospitals, work in friendly co-operation with them. It should also be remembered that many convalescent homes are maintained by charitable bodies and by trade societies for the benefit of members and their dependants. A tentative survey shows that of the larger hospitals in Great Britain (those with about 100 beds and over), 17 out of a total of 30 in London have a convalescent home or fund; in other parts of England and Wales 56 out of a total of 117 have such provision; in Scotland 10 out of a total of 16 have a home or fund. These figures relate only to cases in which the home or fund has a definite connexion with a particular institution, and take no account of the numerous anonymous units which exist to meet the needs of convalescent patients.

ORGANIZATION OF CHILD GUIDANCE CLINICS

DR. R. H. CROVIFY, senior medical officer of the Board of Education for England and Wales read a paper in the Section of Educational Science at the meeting of the British Association at Glasgow, in which he discussed the organization of child guidance clinics in the light of knowledge gained from his visit to the United States last autumn on behalf of the Child Guidance Council. After describing the clinics he saw in America, he drew several conclusions of considerable importance with regard to the possibility of multiplying such clinics in Great Britain. He emphasized the importance of associating closely child guidance clinics with the highly developed school medical service, and took the view that, though in the United States there were two organizations of educational psychology and child guidance, developing to a large extent independently of each other, yet in this country it seemed unlikely that such a dual

¹ René Théophile Hyacinthe Laennec. A Memoir. By Gerald B. Webb. M.D. New York: Paul B. Hoeber Inc. 1928. (Post 8vo pp. xix + 146, 13 plates. 2 dollars net.)

² *British Medical Journal* January 1st 1927 p. 29

service would be adopted. He did not suggest that no development of these clinics should take place apart from the local educational authority, but rather that there should be a close co-operation. Thus the active interest of the local authority should be won for a clinic, even though not directly initiated, financed, or controlled by it. Dr Crowley paid high tribute to the child guidance work already existing in Great Britain, mentioning clinics at various hospitals and institutions, both medical and educational. He referred particularly to the outstanding work of Professor Cyril Burt as psychologist to the London County Council, and to that of Dr Robert Hughes, school medical officer of Stoke-on-Trent. We have previously referred to the inauguration of the Child Guidance Council, which proposes to establish next year a clinic in London through the generosity of the Commonwealth Fund of New York. The clinic has secured the full co-operation of the London County Council, which will be represented on the managing body. Dr Crowley hoped that effective clinics on a less ambitious scale would be established before long to serve the needs of smaller institutions. These would doubtless be the outcome, as a rule, of voluntary initiative in their early stages, and later on the time would come to consider how this work could best be related to other already existing activities.

THE DEATH PENALTY

THERE is a National Council for the Abolition of the Death Penalty, which has Lord Buckmaster as its president. The council has determined upon a forward movement for the attainment of its object, and in a letter to the *Times* Lord Buckmaster sets out the propositions (1) that recent events—notably the result of the Slater appeal and the Home Secretary's eleventh hour reprieve, because of an 'element of doubt' of the three men convicted of the Brighton murder—have raised the capital punishment issue in an acute form", (2) that "its abolition by Parliament without the assurance of public support would be premature", and (3) that "there remains but one constitutional way in which public opinion can find expression" on this subject—namely, "a national petition to Parliament." He appeals to "all those whose considered opinion it is that the death penalty could be dispensed with" to sign such a petition. With the form of petition his council has issued a memorandum giving eleven reasons in support of it. The matter is a serious one, and Lord Buckmaster's support is very weighty. It may nevertheless be doubted whether there really exists any strong public opinion upon this question which requires expression, whether recent events, important as they are, can be said to have made the issue an acute one, and whether any petition to Parliament can really be taken to indicate either the volume or the intensity of such public opinion as there is. Individual reasons for signing a petition are numerous, and the signature can by no means usually be regarded as the result of a "considered opinion." The public mind on this matter is probably in a condition of indifference or uncertainty. It seems unlikely that if any Government proposed to abolish the death penalty there would be any great volume of opposition to such proposal. On the other hand, a great deal of propaganda is necessary if Governmental action is to be undertaken only as the result of public pressure. The petition and accompanying memorandum now before the public may be regarded as useful propaganda, though of the eleven stated reasons against capital punishment some are much less weighty than others. A further excellent piece of propaganda recently published is a little book by Charles Duff entitled *A Handbook on Hanging*. Its title-page, in the old style, describes it as

"a short introduction to the fine art of execution containing much useful information as well as data and wrinkles for hangmen to which is added a Haugman's Ready Reckoner." It is a remarkably effective sustained piece of irony, not unworthy to be mentioned with those masterpieces in the same line, Fielding's *History of Mr Jonathan Wild the Great* and De Quincey's essay on *Murder Considered as one of the Fine Arts*, and can be strongly recommended either to those who do not object to gather their facts and arguments in a somewhat gruesome medium or to those who can enjoy an ironic effort purely for its literary merits.

THIS year's Norman Lockyer Lecture, arranged by the British Science Guild, will be given by Professor J. Arthur Thomson on the afternoon of Wednesday, November 28th, in the Goldsmiths' Hall, London. The subject will be "The culture value of natural history."

USE OF CLOVER'S INHALER IN TONSILLECTOMY AND REMOVAL OF ADENOIDS

BY

SIR CHARTERS J. SIMONDS, K.B.F., C.B., F.R.C.S.,
CONSULTING SURGEON TO GUY'S HOSPITAL

IN response to personal requests and an invitation from the Editor of the *Journal*, I give a brief description of the employment of Clover's inhaler for inducing anaesthesia in the removal of tonsils and adenoids. In doing so let me first say that my communication (September 8th, p. 455) was in no way intended to suggest that ether was not widely used for the open method is now generally employed, though there are advocates for chloroform and ethyl chloride, nor do I presume to instruct the anaesthetists, to whom all methods must be familiar.

First one must gain the confidence of the child and eliminate fear as far as possible. Let the child blow up the bag as it would a balloon, then adjust the face-piece, and ask the child to blow it up, removing the face-piece two or three times so as to get the bag filled. The second and important stage is to allow rebreathing of the air until the face becomes dusky, by which time the child will be rendered so far unconscious as not to detect the admission of ether, which is now gradually admitted. If the child struggles after a few inhalations of ether, this is due to the CO₂, and will be checked by admitting air, not by increasing the ether. If there be no struggling, remove the face-piece when the cyanosis increases, and allow three breaths of air, when the immediate return of colour is evidence that it is due to the CO₂ and not ether.

At this time the child will be so far insensible that the ether can now be admitted without a check until full anaesthesia is obtained. It is necessary to remove the face-piece and admit free air from time to time, for in this stage there should be no cyanosis. Air must also be admitted in this stage should there be any struggling.

When the conjunctiva has become insensible and has remained so for a minute or longer, the face-piece is removed, and if after three or four full breaths it remains insensible the anaesthesia should last for four minutes or more. Should the child move or the conjunctiva become sensitive more ether should be given. It requires some practice and judgement to know when to admit the ether, and how long to continue before removing the face-piece and admitting air.

It will be noticed that rebreathed air produces the first stage of unconsciousness, and there being no objectionable odour the fear of suffocation is almost eliminated. One great advantage over open ether is the absence of mucus, with the associated coughing and congestion. Many children cannot submit without fear and struggling, and must be controlled, but it is remarkable how quickly they settle down under the rebreathed air.

The same procedure answers in adults, omitting, of course, the preliminary play.

POST-VACCINAL ENCEPHALITIS

REPORT BY THE LEAGUE OF NATIONS COMMISSION.

THE Commission on Small-pox and Vaccination of the Health Organization of the League of Nations has issued a memorandum reporting the findings of two of its sub-committees, one on post-vaccinal encephalitis, and the other on the preparation and preservation of vaccine lymph. The former report derives much of its information from English sources, and quotes extensively from the Rolleston Committee's report that was summarized in the *British Medical Journal* of August 11th, 1928 (p. 266).

The Commission emphasizes the fact that post-vaccinal does not necessarily imply pre-vaccinal, that in view of the millions of vaccinations that are carried out in any given year there must always be present in the community very large numbers of people subject to the ordinary chances of life, and *incidentally* under the influence of the vaccine virus. Such people are no more immune from disease of the brain and nervous system than anyone else, and there is therefore, no reason why the coincidence of vaccine with a true encephalitis should not be expected to occur. Encephalitis, moreover, occurs as a complication of numerous infections—for example, measles and various forms of toxæmia—and in so far as vaccine is an infection it might be considered legitimate to regard the cases under consideration merely as instances of ordinary post-infective encephalitis. The Commission, however, is of opinion that there are at present practical reasons for considering post-vaccinal encephalitis as a separate pathological and clinical entity. Particularly in Holland and in England have the cases been numerous enough to merit collective consideration.

The Comparative Incidence of Cases

The risk of post-vaccinal encephalitis may easily be exaggerated; indeed, in Holland it has been considered sufficiently grave to cause temporary suspension of the laws relating to the vaccination of children, and in England it has received the attention of two separate Ministry of Health Committees—the Andrews Committee of 1924, and the Rolleston Committee of 1926. In actual fact, during the whole period 1923-27, only 139 cases of disease of the central nervous system following vaccination were reported in Holland, 41 being fatal. In England and Wales 62 cases, with 36 deaths, occurred between November, 1922 and November, 1923, and a further 25 cases, with 12 deaths, between January, 1926, and September, 1927—the periods reported on by the two committees.

The age distribution in the incidence of post-vaccinal encephalitis is of particular interest. The bulk of the cases occur in children between the ages of 3 and 13—infants and adults being almost wholly immune. Moreover, the disease follows the revaccinations of older children and of adults with the utmost rarity, a fact which, taken in conjunction with the almost complete immunity of the first two years, provides ample reason for emphasizing the value of undertaking prophylactic vaccination against small-pox as early as possible in life.

Outstanding Clinical Features

In nearly every instance the complication has occurred in cases of vaccine of normal appearance apparently running a normal course. No single method of vaccination has been specially implicated, nor have any particular strains of lymph or methods of preparation been concerned. A noteworthy fact is that both in England and Wales, and in Holland it has been especially in the less populous rural areas that vaccination has been followed by encephalitic complications.

The correspondence observed in the early Dutch cases between post-vaccinal encephalitis and the local distribution of true encephalitis lethargica has not been observed in England or maintained in Holland, indeed, the clinical history and pathological findings of cases of post-vaccinal encephalitis justify the conclusion that one is dealing with two separate diseases. Interesting clinical features of post-vaccinal encephalitis are the incubation period—which is between the ninth and thirteenth day following vaccination, with marked preference shown for the eleventh day—and the sudden onset with four cardinal symptoms

of headache, vomiting, drowsiness, and pyrexia. The extremes met with are mild cases which apparently recover completely in a week (though in a few of these mental deterioration and residual paralysis have been reported) and severe cases which develop extensive spastic paralysis and pass rapidly into coma and death. Between these extremes are met cases of every grade of severity. The cerebrospinal fluid is commonly under pressure but is sterile. Pathological examination of fatal cases shows the presence of diffuse encephalo-myelitis with perivascular infiltration and oedema. In some cases the histological changes resemble those of acute disseminated sclerosis, and in all cases they differ essentially from those met with in true epidemic encephalitis.

The general conclusion of the Commission is that the virus of vaccine cannot of itself be considered responsible for encephalitis. It considers rather that some unknown factor—perhaps a filter-passing virus or a latent virus—determines the occurrence of the complication in question.

PREPARATION AND PRESERVATION OF LYMPH

The sub-commission on the preparation and preservation of lymph dealt with the factors which may favourably or unfavourably affect its value as a vaccine. It concluded that only the treatment to which the lymph seed is subjected determines the quality of the lymph, the origin of the strain used being of no significance in this connexion.

The virulence of the vaccine virus is sometimes maintained when it is carried in unbroken series from calf to calf, inoid usually it is found necessary to interpolate some other passage in the series, commonly the rabbit or to secure a retro-vaccine, commonly a lymph obtained from man. These methods appear to be unobjectionable. On the other hand, neurolymph obtained by intra-cerebral injections into rabbits, and testicular lymph, sometimes display properties that differ from ordinary vaccine, and conclusions as to their effects on man cannot yet be formulated.

Veterinary Control

The Commission, while not dealing with the technique of preparing lymph ready for issue, emphasizes the vital need for veterinary control of the animals used such control involving examination of the living animal before inoculation and the slaughter and *post-mortem* examination of the animal as soon as the vaccine has been obtained. The lymph should be used only when the results of these examinations are unexceptionable, and, in particular, when there are no signs of tuberculous lesions.

Preparation and Employment of Lymph

Questions relating to the employment of diluted vaccine have been specially considered. Dilution of lymph does not necessarily imply loss of virulence, it being better to employ a strain of more than minimal standard, diluted, than one of weak virulence undiluted. But investigations still need to be made into the durability of dilution, the nature of the diluent, the degree of dilution and the actual clinical results obtained from diluted lymph.

The Commission is strongly of opinion that the medical officers of vaccine institutes should themselves undertake human vaccination in order to study the potency of the lymph they make. The bare report "successful or unsuccessful" is of no value when the vaccine reaction is not described to them in detail. In primary vaccination the percentage of *insertion successes* should be noted in revaccinations the reaction should be described in official records as one of three classes:

- 1 Reaction of the primary vaccination type (Jenner's pustule)
- 2 Accelerated reaction (vesicular reaction), modified vaccine
- 3 Allergic or early reaction (papular reaction)

The Commission recommends that the technique and methods of vaccination permitted and recommended in different countries should be carefully defined the results duly recorded, and then judged in respect of actual immunity afforded on exposure to small-pox or on revaccination. In this way a satisfactory technique for universal adoption may ultimately be evolved. It concludes by reasserting its conviction that vaccination remains the most powerful weapon against small-pox we possess, and strongly advocates primary vaccination in early infancy rather than at the later ages of childhood.

Scotland.

William Mackenzie Medal

THE presentation of the William Mackenzie Medal "for valuable contributions to ophthalmology" to A. Maxfield Ramsay, M.D., LL.D., consulting ophthalmic surgeon to the Glasgow Royal Infirmary, will take place at the Glasgow Eye Infirmary, on Tuesday, October 9th, at 8 p.m. Dr Ramsay will deliver an address on the importance of general methods in the treatment of eye disease.

Health of Glasgow in 1927

Dr A. S. M. Macgregor, medical officer of health, in his annual report for 1927, gives the population of Glasgow, based on inhabited houses, as 1,130,675. The density of population of the city is 38 persons per acre, the highest ward density being 222 persons per acre in Woodside Ward, which is almost wholly occupied by tenement property. The birth rate of the city in 1927 was 20.85 per 1,000—lower than last year and the year before—while the death rate of 13.66 per 1,000 was also lower than the last two years. The death rates from pulmonary and non-pulmonary tuberculosis, 838 and 301 per million, were the lowest on record. The ultra-violet ray clinics of the corporation are continuing to do good work, at the Cochrane Street clinic better results have been obtained by the use of the carbon arc followed by the mercury vapour lamp than by the use of either lamp alone. In rachitic children under 24 years straightening of the legs is commonly observed, and even in older children, who have been followed up, a progressive diminution of deformity has taken place. Impetigo, furunculosis, and septic lesions have cleared up quickly under the vapour lamp, pregnant women and nursing mothers have derived much benefit from the clinic. An outbreak of paratyphoid B fever in Possilpark was traced to a milk supply. Under the maternity and child welfare schemes 34 syphilitic expectant mothers received anti-syphilitic treatment, and 20 of these bore healthy children. There were 2 stillbirths, 3 infected children, and 1 miscarriage, while 8 pregnancies had not terminated at the time of writing. Eight pregnant women suffering from gonorrhoea were rendered non-infective before the onset of labour, and their children escaped ophthalmia. The pressure of the common communicable diseases, including pneumonia, measles, and whooping-cough, made it necessary to divert a phthisis ward from its normal uses, and also to employ the country homes at Scotstoun and Mount Blow to relieve the hospitals by taking in convalescent children. Acknowledgement is made of assistance received from the officials of Glasgow Parish Council, who without demur made their hospital wards available for patients with acute pneumonia. For a brief period during the year all cases of pneumonia and measles could not be taken into the hospitals of the city. Those on the waiting list were visited daily at home by nurses specially detailed, and very urgent cases were selected for priority of admission. The policy of the general hospitals of restricting admissions of pneumonia cases threw further pressure on the accommodation of the local authority. Bronchitis, too, was being sent in as pneumonia, and medical practitioners were invited to exercise the utmost discrimination before making a request for the admission of such cases. Under the bacteriological section of the report attention is drawn to the superiority of the naked-eye method of carrying out Widal's reaction over the microscopic method. The medical practitioner should send in 2 to 3 c.c. of blood, and not the content of the capillary tube. At the same time, the value of the blood culture during the first week of suspected typhoid fever should be kept in mind. Illness was produced in several members of a family by tin dissolved in the juice of tinned apricots. Symptoms of poisoning in three young children, alleged to be due to the eating of apples, were traced to aconite contained in cascara sagrada, given out by an institution in a bottle which had previously held ABC Liniment. Among many other matters of interest dealt with in the report are the natural presence of arsenic in shellfish, the use of hydrocyanic acid gas as a fumigant

for flour, the standards attained by designated milks, the use of gas firing for smoke prevention in one of the metal trades, the incidence of bone tuberculosis, and the standardizing of scarlet fever antitoxin. The housing question, too, is carefully explored on its social side, and views as to the standards of cleanliness which should be expected from tenants suddenly transferred from a slum to a rehousing suburb are expressed in a considerate manner.

Voluntary Patients in Mental Hospitals

In his annual report for the year ended March 31st, Dr W. D. Chambers, physician superintendent of James Murray's Royal Asylum, Perth, discusses the policy followed at this institution—and other royal mental hospitals in Scotland—of encouraging voluntary admissions. The increasing proportion of such admissions has, he states, proved the success of this policy, and he believes that when the method comes into use in the country mental hospitals, where for the time being its development is hindered by certain technical difficulties, its success and value will be even more obvious. Figures covering the past seven years are quoted showing that of voluntary patients admitted in this period 39 per cent were discharged as recovered and 29.1 per cent as improved, the corresponding figures for certified patients being 30.1 and 27.5 per cent. Dr Chambers expresses the opinion that the more favourable results among voluntary patients are only partly due to the illness being less severe and to the earlier entry which is common in this class. He believes these results are to some extent attributable to the feeling of spontaneous co-operation which is induced in voluntary patients by the knowledge of their status and to the absence of irksome feelings of compulsion and restraint. After recalling that not long ago certain patients were certified who would willingly and most suitably have entered the institution for treatment spontaneously Dr Chambers states that it is now more common to encounter patients, brought by their friends for admission on a voluntary basis, who are quite unsuitable for this. He remarks that this attitude is often found in the lay mind, and emphasizes the fact that there will always be a considerable number among mental invalids who urgently need care and treatment for their own safety and welfare and the protection of the public, and who, owing to lack of insight, are quite unfit to exercise judgement or control in the matter of their own disposal. Some form of legal machinery is indispensable in these cases, and attempts to provide for them without their own consent and without proper legal authority will, he believes, undoubtedly lead in due course to the appearance and growth of "homes," under private and anonymous proprietors, where such patients can be received, secluded, and detained. Dr Chambers points out the difficulty of securing adequate care by such means, stating that the right place for the treatment of a case of mental illness of average severity—a condition which is likely to require special treatment for from two to six months, or longer—is within a special hospital established, equipped, staffed, and structurally designed for the purpose, having a spaciousness and general atmosphere very different from the environment which makes for the successful treatment of acute but transient medical and surgical conditions.

A Medical Family

In August, 1828, Matthew Baillie Gairdner became a licentiate of the Royal College of Surgeons of Edinburgh, at the early age of 19, he graduated M.D. at the University of Edinburgh two years later, and became F.R.C.S. Ed. in 1858, he died in 1888. His oldest son, James, graduated M.B., C.M. Ed. in 1857, proceeded M.D. in 1873, and has acted as medical officer of Crieff Parish in Perthshire for more than sixty years. The professional practice of father and son has thus covered more than a century. It would be interesting to know if this record can be approached by any other medical family. Dr James Gairdner's younger brother, Matthew William Gairdner, graduated M.B. Ed. and obtained the diploma of L.R.C.S. Ed. in 1871, he resides at Cheltenham and his son, Alan Campbell Gairdner, is a medical graduate of Oxford and obtained the F.R.C.S. Eng. this summer.

England and Wales.

Tuberculosis in Birmingham

THE report on tuberculosis in Birmingham in 1927, issued from the public health department, contains, in addition to the usual statistical information, detailed reports by the chief tuberculosis officer, Dr G B Dixon, on the antituberculosis centre, sanatoriums, and treatment in the light centre. Dr Dixon refers to the contention that it is inadvisable to admit to a sanatorium any patients but those whose circumstances and clinical condition suggest that arrest of the disease is probable, and to the persistent advocacy of hospitals for the segregation of advanced cases of tuberculosis. In practice, he says, it has been found that the most suitable solution of those two problems lies in the provision of pavilions or wards for the "hospital" type of case in most of the sanatoriums. Experience has shown that the advanced and bedridden patient is, as a rule, willing to enter such a pavilion when it is attached to a sanatorium, while a large majority of those who fall within the category of "hospital" cases not only refuse to enter an institution set apart solely for advanced cases, but resent the suggestion that they should do so. Hospitals provided for this purpose quickly acquire a sinister reputation from the large number of deaths recorded, and this is repellent to the sufferer and to those from whom the medical, nursing, and domestic staffs are recruited. There has been a marked decrease during the past decade in the number of cases of patients notified in Birmingham as suffering from pulmonary tubercle, which is regarded as very satisfactory. At the same time the number of suspects notified has increased, suggesting that the diagnosis of this disease is being left more and more in the hands of the medical staff at the centre. The tables show that during the past ten years the number of new cases of all forms of tuberculosis recorded has been reduced to less than half, while the number of deaths has fallen by about one-third. In regard to pulmonary tuberculosis, the number of new cases in 1927 was equal to 1.39 per 1,000 of population, against 3.42 per 1,000 of population in 1917, the death rate from this disease fell from 1.30 per 1,000 in 1917 to 0.69 per 1,000 in 1927.

Royal Victoria Infirmary, Newcastle-upon Tyne

THE report of the Royal Victoria Infirmary, Newcastle-upon-Tyne, for 1927 again refers to the need for increased accommodation to relieve the overcrowding which exists in the wards and to afford improved facilities for the treatment of special cases. Large numbers remain on the waiting lists. It is suggested that extended convalescent accommodation, adequate and suitably situated to permit continued and rapid transfer from the infirmary, would solve many of the present difficulties. In the course of the current year certain premises adjoining the main buildings, and occupied by the Ministry of Pensions, revert to the infirmary, and consideration is being given to the question of their utilization. It has been suggested by the honorary medical and surgical staff that part of the premises should be adapted as wards for paying patients. Meantime it has been decided to proceed with an extension scheme, and a public appeal for £150,000 has been launched. This sum is intended to provide for the adaptation of these buildings for civil requirements, for the extension of the out-patient departments, and for increased accommodation for the nursing and domestic staff. The appeal is addressed to the counties of Northumberland and Durham, and to Newcastle-upon-Tyne, all of which are served by the infirmary, and attention is directed also to its importance as one of the twenty-two great teaching hospitals of Great Britain. Motorists and road users are reminded of their special interest in the infirmary, it is stated that road accidents dealt with recently have amounted to an average of twenty per week, sufficient to occupy the greater part of a ward throughout the year.

University of London Medical Graduates' Society

A dinner for members of the recently formed University of London Medical Graduates' Society will be held in London towards the end of October, and it is expected that dinners in Birmingham and Leeds will be held some time in November. The society, membership of which is open to all medical graduates of the University, was formed last year, and held its first annual dinner in May last, with Sir Berkeley Moynihan in the chair. Nearly two hundred life members have enrolled to date, but the society hopes soon to secure the adherence of a much larger proportion of the 4,500 graduates in the medical faculty of the University of London. The constitution provides that it shall have no political activities, but shall be chiefly social, its objects being to bring medical graduates of the University into closer relationship with it and with one another, to keep in touch with overseas medical graduates of the University, and to promote the interests of the University and its medical members. Sir StClair Thomson is president for the current year, the vice-presidents being Sir John Rose Bradford, Sir Berkeley Moynihan, and Dame Mary Scharlieb; the honorary treasurer is Mr W McAdam Eccles, and the honorary secretaries are Dr C A H Franklin and Dr Dorothy C Hare, to whom applications for membership and requests for information should be addressed, at 11, Chandos Street, Coventry Square, London, W 1.

The Middlesex Cancer Hospital

THE Cancer Charity of the Middlesex Hospital, founded as long ago as 1792, has been for many years housed in a special wing with its own separate cancer wards, its own equipment, organization, accounts, research work, and records. In the report for 1927, recently presented to a Court of Governors, it is recorded that the name of "The Middlesex Cancer Hospital" has now been adopted to emphasize the special nature of the charity and to enable the public to distinguish the special work against cancer which continues to be the main object of the institution. The honorary staff of the parent hospital attends the "Cancer Hospital," and the cancer research work is closely linked up with all the pathological work of the Bland Sutton Institute in the Medical School. In patients are admitted in the incurable stage "until relieved by art or released by death," and operable cases are admitted under the same system as obtains in the general wards. There were 555 patients admitted during the year 1927 with an average length of stay of just over seven weeks and new patients attending the out-patient department numbered 176. At the end of 1927 a special appeal for the Middlesex Cancer Hospital was launched, and donations have already shown an increase.

Correspondence.

ALKALIS AND NEPHRITIS

SIR,—Professor Gillman Moorhead in his opening address on acute nephritis in the Section of Medicine at the Annual Meeting of the British Medical Association, published in your issue of September 22nd (p 515), refers to some observations of mine concerning the use of alkalis in the prevention of scarlatinal nephritis. Since the publication of the figures quoted by Professor Moorhead, Dr Carter and I have continued the investigation, the latest results being as follows: Of 1,280 cases of mild scarlet fever treated throughout the illness (five to six weeks) with alkalis, 5 developed nephritis—that is, 0.4 per cent. Of 914 control cases of scarlet fever, observed simultaneously with the former, not having alkalis, 43, or 4.7 per cent, developed nephritis. In very few cases was it necessary to give more than 200 grains of alkali in the twenty-four hours, often less. No objection to this dose was made by any of the patients, and really large doses—that is, over 400 grains a day—were never given. Professor Moorhead also quotes Dr Peters's figure claiming that alkalis did not lessen the incidence of nephritis in 8,000 cases of scarlet fever observed by him.

I have already pointed out¹ that Dr Peters's figures cannot be compared with ours, because in his cases alkalis were only given during the first week of the disease, whereas nephritis rarely occurs until later.

With regard to Stieglitz's statement that excessive doses of alkalis may actually cause or predispose to the onset of nephritis, I quite agree, although I may perhaps be allowed to point out that I have never advocated the giving of excessive, but only of sufficient, doses. Incidentally it should be noted that Stieglitz's general conclusions concerning the danger of giving alkalis in nephritis, which have been extensively quoted, were based on experimental work which has not been entirely confirmed.²

Lastly, in your leading article in the same issue, Professor Moorhead is stated to have said that "his experience does not lend him to support the vigorous alkaline treatment of nephritis advocated by Martin H. Fischer of Cincinnati, and more recently employed by A. A. Osman." It is not quite clear from the context whether this opinion refers to the vigorous alkaline treatment of acute or chronic nephritis. This is a point of the greatest importance, as I have never suggested the giving of large doses of alkalis in the routine treatment of acute nephritis, on the contrary, I have been careful to point out³ that such a procedure may be dangerous. In certain cases of chronic (tubular) nephritis, on the other hand, there is abundant evidence that large, but carefully controlled, doses of alkalis will often prove effective where all other methods have failed—I am, etc.,

London S.E. Sept. 24th.

A. A. OSMAN

PULMONARY ASBESTOSIS

Sir,—Pulmonary asbestosis has become a question of international interest and importance, and it is essential that every statement concerning the disease should be carefully considered in the light of known facts. Renders of Professor M. J. Stewart's letter in the *Journal* of September 15th (p. 509) will carry away three impressions that are not in accordance with the results of my own work on asbestos and the "curious" bodies.

The first impression given by the letter is that the curious bodies found in the lungs are diagnostic of pulmonary asbestosis, the second, that these bodies are actual derivatives of asbestos, and the third, that these bodies are emphatically not vegetable in origin. The work is not yet complete, but Professor Stewart's letter necessitates this preliminary note.

The first case actually proved to be due to the inhalation of asbestos dust was published in the *British Medical Journal* in 1924.⁴ The proof did not include the presence of the curious bodies, but rested upon the demonstration of actual particles of asbestos fibre and dust in fibrotic and necrotic areas of the lungs. I have examined scores of samples of asbestos from different countries, and can make this definite statement: the curious bodies do not exist in asbestos nor can they be produced from asbestos by any known chemical means.

The curious bodies can be isolated from the lungs in a practically pure state either by pulling portions of the lungs into small fragments and extracting with water or saline, or, as Professor Stewart himself suggested, by the action of trypsin. They are present in enormous numbers, and sufficient material can be obtained for analysis. During the work three facts have been brought to light. They do not polarize light; they contain less iron as Fe_2O_3 than the erythrolytic dust in which the patient worked, and—this is the important point—they do not give a distinctive x-ray pattern by the method devised by Professor Bragg.

These results completely negative the theory that the bodies are asbestos or actual derivatives of asbestos.

If cultures of organisms—staphylococci, for example—are incubated with a colloidal solution of asbestos they become silicated, and their appearance and staining reactions completely changed. The cocci appear 2-3 μ in diameter,

of a golden brown to a light yellow in colour, and do not stain by the usual methods. They closely resemble the discs and separate particles of the curious bodies found in the lungs. The silicated organisms are being subjected to the action of currents in the hope that replicas of the curious bodies will be produced. Work is continuing on colloidal silica solutions made from substances other than asbestos, and I do not see any reason why they should not act in the same manner.

There are fewer than ten cases of pulmonary asbestosis on record, and although the curious bodies have been found in all of them, much more work is necessary before definite views can be expressed. So far the experimental results suggest diametrically opposite conclusions to those drawn by Professor Stewart. They suggest the possibility of the curious bodies being present in other conditions connected with silica, they negative the idea that the bodies are asbestos or actual derivatives of asbestos, and strongly point to the main bulk of the bodies being actually vegetable in origin. The nucleus upon which the bodies are built is possibly asbestos in these particular cases, but even this remains to be proved—I am, etc.,

The Pathological Department
Wigan Infirmary, Sept. 18th.

W. E. COOKE

SAFETY IN ANAESTHESIA

Sir,—The very interesting controversy in regard to the best anaesthetic for the guillotine operation for tonsils and the removal of adenoids has gradually centred itself, as seems right and proper, upon the question of safety and efficiency. This is very satisfactory to those of us who were rather appalled by the account of the method (with speed as the primary consideration) which "permitted of thirty patients being operated on in an hour" by use of ethyl chloride. It is still more refreshing to see the advocacy of ether, advanced first by Sir Charters Symonds with his long experience, and later by Dr. Wright Lambert and Dr. Watson-Williams.

For some years we have used open ether alone, preceded always by atropine, for all such operations, and I would contend that

- 1 It is the only really safe anaesthetic for such cases.
- 2 It gives the operator plenty of time to do his work efficiently and to minimize haemorrhage.
- 3 It tends directly towards the prevention of shock, whereas chloroform and ethyl chloride rather encourage it.
- 4 The patient remains largely oblivious to pain for a much longer period than with other anaesthetics.

In general I believe profoundly that the employment of ether for all operations, except in the rare instances where it is contraindicated, is the only way by which the anaesthetist can secure peace of mind for himself and safety for his patient. I am referring, of course, only to those cases where the issue is between ether on the one hand and chloroform and ethyl chloride on the other.

Personally I always use ether, by the open method or in a Clover's inhaler, in obstetric practice, and, although I am aware that many would regard the abandonment of chloroform in midwifery as a heresy, I strongly advocate the use of ether for the following reasons:

- 1 It is safer, especially where rapid induction is necessary, and it is then that a Clover is invaluable.
- 2 It does not abolish the uterine contractions to nearly the same extent as does chloroform.
- 3 It does not interfere with retraction, and therefore is much less likely to be associated with severe post partum haemorrhage than is chloroform.
- 4 There is no fear of 'delayed poisoning' with prolonged administration.
- 5 The patient often remains analgesic for a considerable time after administration has ceased, and lesser degrees of perineal tears can often be dealt with without more anaesthetic.

The two special conditions where chloroform would seem to be more advantageous are in rigidity of the cervix and in tonic contraction of the uterus—I am, etc.,

MIM HUI, Sept. 22nd.

ANAESTHESIA FOR TONSILLECTOMY AND REMOVAL OF ADENOIDS

SIR,—Dr P Watson-Williams has asked me to correct an error in his letter published in the *Journal* of September 22nd (p 547). It was in the year 1897, not 1887, that the "two-hotto" method of administering ether and chloroform was introduced in the Bristol Royal Infirmary. The method was based on the belief that there was some admixture of these drugs, suitable for each and every occasion, and that this could only be obtained by a system, such as the above, which enabled the administrator to vary the proportions, from time to time, as indications demanded.

It was soon found that in most instances, chloroform was not needed after anaesthesia had been established, and that in many cases ether alone on the open mask was sufficient even for induction. The claims for this method were not only that it produced a minimum of toxic saturation, but also that it provided a safe and easy stepping-stone to open ether for those administrators who hitherto had been accustomed to use chloroform alone upon the open mask. By substituting the open for the closed method of giving ether it was found that the tendency to haemorrhage was practically obviated, a finding which we have confirmed in a large experience of open ether in general and nose and throat anaesthesia, showing that with the closed method the greater tendency to bleed should be attributed to some other factor than ether, such as engorgement of the mucous membrane and the accumulation of CO₂.

This subject seems worthy of very careful consideration, and I am glad to have this opportunity of endorsing Dr Watson-Williams's views as expressed in his letter—I am, etc.,

Clifton Bristol Sept. 22nd.

ARTHUR L FLEMING

* * We publish at page 581 this week a note by Sir Charles Symonds on the use of Clover's inhaler in tonsillectomy and removal of adenoids.—ED W W J

INTESTINAL AMOEBIASIS IN BRITAIN

SIR,—I was much interested in the case, reported by Dr J Campbell Gilroy, of tropical liver abscess occurring in England, published in the *British Medical Journal* of September 22nd (p 529).

In a communication by Dr P H Manson-Bahr and myself, published in the *Transactions* of the Royal Society of Tropical Medicine and Hygiene, vol xxii, No 2, August, 1928, we reported five cases of intestinal amoebiasis occurring in Northern Europe, four of which occurred in France and one in Germany. None of these was complicated by liver abscess.

It would be interesting to know of other indigenous cases occurring in this country as it seems highly probable that with the presence of so many ex-service and other "carriers" cases do occur here but pass unrecognized.

As Dr Gilroy points out, the importance of routine examination of stools in all cases of persistent diarrhoea cannot be over-emphasized—I am, etc.,

HUGH WILLOUGHBY, M R C S, L R C P,

Gravesend Sept. 22nd

D T M and H

STEREOSCOPE AND BINOSCOPE

SIR,—There seems to be difficulty in recognizing the difference between the stereoscope and the binoscope as a means for treating cases of squint even a distinguished ophthalmologist has written pointing out that the difference is not apparent. Will you kindly allow me to make a short statement in the *British Medical Journal* to render the subject clear?

In the use of the stereoscope two objects (pictures) are employed, and each eye sees only the picture which it is intended to see. The field of vision of each eye is thus completely screened from that of the other, and no real object is seen by both eyes, which can be fixed by both in binocular vision. To supply such an object the two pictures are made to appear to occupy the same place and to

appear as one, and it is this fictitious object, formed by the fusion of the two pictures by the apparatus itself, which the two eyes are able to fix in binocular vision. When a person with normal vision looks through a stereoscope he is able to adjust it by means of his binocular vision so that the two pictures appear as one object.

In squint and other defects of binocular vision it is doubtful whether adjustment is ever accurate, and the stereoscope fails as a means of treatment. The binoscope, by presenting to both eyes in the central unscreened part of the field of vision the same actual objects, instead of the fictitious substitute employed in the stereoscope, induces binocular vision without difficulty, and succeeds as a means of treatment.

In using the binoscope the screened lateral parts of the field of vision bring about simultaneous vision, and binocular vision of objects in the central unscreened part of it readily follows in most cases of squint, so that the squint at once disappears for the time, and its permanent disappearance is effected by systematic daily use—I am, etc.,

KENNETH R SMITH, M D

Richmond Surrey Sept 13th

THE REPRINT PLAGUE

SIR,—The invention of printing has been attended with many evils, but its advantages are so great that we must put up with its disadvantages. But not much can be said in favour of the more modern invention of reprinting. No sooner does an author—especially a scientific author—have the good luck to get his paper printed in some reputable journal (the adjective is not essential) than he proceeds to splash with a cataract of reprints, not only his friends, who have to grin and bear it, but also crowds of persons upon whose forbearance he has no claims whatever.

It is true that these persecuted people generally "lose no time" in reading such effusions, and it may be doubted whether an author gains a commensurate advantage for his expenditure of so much hard cash in postage. Here I had better confess that I am an offender myself, or someone may give me away. An editor recently offered me a hundred reprints of an article of my own, and I was base enough to take fifty. My friends don't spare me, and I see no reason why I should spare them. But this does not affect the morality of the proceedings, moralists can generally give good reasons for condemning a practice in which they themselves indulge.

I calculate that about 4 per cent of those to whom reprints are sent actually read them, and they belong to one or other of two classes. (1) kind hearted and conscientious men and women who think it their duty to read and acknowledge these inflictions, (2) friends. As to the first class, these kindly persons lead miserable lives and, since they are the salt of the earth and so few, it is our duty to do something to protect them. Even friends deserve some little consideration. It is an awkward moment for both when first one meets a friend after having sent him a reprint. He is not a liar or one would not have chosen him for a friend, but neither is he usually a saint, and if he can persuade us that he has read and admired our lucubration without actually saying so, it does not weigh very heavily upon his conscience, for self-preservation is Nature's first law.

It is to be feared that the two main causes of the "reprint plague" are vanity, and a desire to extend our fame into regions where it would not otherwise have penetrated. But the dividing line between vanity and laudable ambition is so thin that it is difficult to suggest a remedy which will scotch the one without hurting the other, and I am not sure we want to abolish even vanity altogether, the vain man certainly does more useful work than the one suffering from a sense of inferiority. The plague is, however, so virulent and widespread that something ought to be done to check its ravages or we shall all sooner or later be victims.

First, then, a few words to the vain man, these can be given without offence because no one who reads this will think that the remarks apply to him. A denunciatory

sermon is always enjoyed for the same reason. As I have said, only about 4 per cent of those who receive reprints will read them, and very few even of these will take the trouble to send flattering remarks to the author. Let him remember that we are speaking of averages. If he sends out a hundred reprints, it may be that these four persons, plus four more, are in the next hundred whom he has not circulated, why take so much trouble to court a possible tragedy?

On the other hand, the man who is merely afflicted with laudable ambition may possibly point to Mendel's fate, and contend that if he had judiciously planted a few reprints where they would have done most good, he would not have had to wait till he was dead before receiving proper recognition. Well, of course, there is something in this, though he should have sent his paper to a journal with a decent circulation.

Because, however, there is something in it, we should not attempt to suppress the plague by abolishing reprints altogether, we must choose a remedy which if not pleasant, is at least harmless. Why not take a leaf out of the procedure of the film trade? I would suggest the setting up of a competent board of scientific censors, whose duty would be to license reprinting by issuing "certificates for universal exhibition" in the case of papers of sufficient merit to warrant it. Having obtained this licence, the happy author could, with a clear conscience, send his reprints to as many people as he liked in the sure knowledge that they ought to read his paper, even if they don't want to.—I am, etc.,

Surbiton Sept 1st

E W ADAMS, MD

THE ERECT POSTURE

Sir,—Many of your readers must have perused with pleasure Professor Colin Mackenzie's interesting and suggestive lecture on the importance of zoology to medical science (*Journal*, September 22nd, p. 534). With regard to the acquisition of the erect posture by infants, may I recall what Harvey says in his *Generation of Living Creatures* (1653), "their first venture to foot it represents them a prone kind of cattle which can scarce exalt themselves to the erection of a cock."

I would like to thank the lecturer for his praise of football, of the benefits of which it is proposed to deprive our police.—I am, etc.,

London W Sept 21st.

HENBERT R SPENCER

SECURITY OF TENURE IN PUBLIC POSTS

Sir,—I notice in your Educational Number that there are given particulars of the various public services open to members of the medical profession. The prospects are, in many cases, enticing, embracing as they do a pleasant, care-free life with gradually rising salary and a pension at the end. But a word of warning should be given to those who think of entering any public service: first of all, inquire what security of tenure is offered.

In services such as the army and navy there need be no doubt. No one can be deprived of his position without a full and open inquiry, and then only for grave misconduct. A large number of public appointments are nowadays held under local authorities, and here, though the doctor is compelled to contribute to a pension fund, there is no security of tenure whatever. A doctor may be given three months' notice at any time, no matter how many years he may have been in the service. If the authority be so minded it can give the doctor three months' pay in advance and tell him to clear out at once. A doctor in one of these services is in just the same position as one's housemaid, to whom one may give notice or give pay in lieu of notice. In entering the service he places his professional reputation in the hands of the authority and there is none to whom he can apply for help if he is suddenly dispensed with. Though the authority is a public body it functions as a private employer, and it cannot be forced to give any explanation for its action. There is no legal redress whatever for the doctor, no matter how seriously his reputation may have been damaged. That the danger of such an occurrence is very real may be learned

by a perusal of some of the reports of medical protection societies.

The promise of a pension which may have been the main inducement to joining the service is thus ephemeral. In law there is nothing to prevent the authority escaping its obligation by giving the doctor three months' notice to leave, just before he becomes eligible for his pension. That, of course, is an extreme case, but the practical inference is that the longer the doctor stays in the service the less secure is his position and the greater the inducement of the authority to get rid of him. As the work in many of these parochial services is of a specialist nature the doctor, after many years spent in one particular branch of medicine, is less able, should he lose his post and his pension, to take up general practice than would be a doctor who had been in practice all his professional life.

Needless to say the doctor's consciousness of his precarious position has a prejudicial effect on his independence of action. To amplify the housemaid analogy it is as if one said to her, "I will pay you so much a week, but every week you must return to me part of your wages. When you have reached the age of 60 and have done thirty years' service I will give you a pension. But I reserve the right to give you a week's notice at any time. If I do so, your chances of getting employment anywhere else will be very small." Most people would say that the housemaid who entered such a service showed a child-like faith in her employer.

For the benefit of those of your readers who may be a little hazy as to who constitute "local authorities" I would say that they are such bodies as boards of guardians, county, borough, and town councils with their subsidiaries, public health, watch, and asylum visiting committees.—I am, etc.,

Widmore, Sept 18th

H C McMINSTER

THE PETTIGREWS

Sir,—In his interesting *Novi et Vetera* article on the Brompton Medical Book Society in your issue of September 15th (p. 494), "H R" refers to Dr William Vesalius Pettigrew of Chester Street. This gentleman was mentioned in a previous *Novi et Vetera* article in the *British Medical Journal*, on "An Old Directory," on January 13th, 1900, and he was the subject of an interesting correspondence in the issues of January 20th and 27th of that year. He was the son of a more distinguished man, Thomas Joseph, known as "Mummy" Pettigrew, from his having given a lecture and demonstration on that subject at the Royal Institution, when he spent some hours in unrolling 900 yards of bandages. William Vesalius, his son, claimed the authorship, in his entry in the first (1845) *London Medical Directory*, of an "anonymous" work on the diseases of children.

"H R" comments on the moral courage of the founders of the Brompton Society in fixing the number of its members at thirteen. The ridiculous superstition connected with this number was then much more limited in its scope than it is in this credulous age. Ill luck was confined to the first to rise of a party of thirteen at table. The analogy of the Last Supper is obvious enough. So far from thirteen having been anciently an unlucky number, it seems to have been chosen as auspicious, being the number of Christ and his Apostles, and was quite commonly the number for which provision was made in founding almshouses and such like.—I am, etc.,

London S.W. Sept. 20th.

E MUIRHEAD LITTLE

Universities and Colleges

UNIVERSITY OF LONDON

UNIVERSITY COLLEGE

THE session 1928-29 opens at University College London, on Monday October 1st. Students of the Faculty of Medical Sciences will be received by the Provost and Deans on that day as follows: First-year students between 10 a.m. and 1 p.m., students of inter years between 2.15 and 4 p.m.

Public lectures that have been arranged for the first term includes a course on "Smoke pollution of the air and public health" by Dr John Owens on November 2nd, 9th, and 14th at 5.30 p.m. Sir Napier Shaw will preside at the first lecture. Particulars of

these and other public lectures may be had on application to the secretary, University College, London, W.C.1. A stamped addressed envelope should be enclosed.

The following elections in the Faculty of Medical Sciences of the College have been made:

Entrance Scholarship (£30 a year for three years) C. Qvist (first year)
F. R. Bettley (second year) Bucknill Scholarships P. Gallanck
(500 guineas) D. A. Anderson (50 guineas) Exhibitions (£5 guineas
each) F. J. Jarmalinski J. W. James I. J. Jarmalinski
C. R. Lanyon (second year) D. Joy (first year awarded subject to
completion of the first Medical Course examination in December
1929) Harpe, Physiological Scholarship (£115) F. Ogden B.Sc.
Percy F. Macgregor Research Scholarship in Embryology (£50)
Frances E. Luce B.Sc.

The Services

MEMORIAL TO JAMES LIND

An altar painting in memory of Dr. James Lind, the father of nautical medicine, was unveiled on September 23rd by Surgeon Rear Admiral A. J. Hewitt in the chapel of the Royal Naval Hospital at Haslar, where Lind was physician from 1758 to 1763.

James Lind was born in Scotland in 1716 and at the age of 15 was registered as an apprentice to a Fellow of the Edinburgh College of Surgeons, subsequently becoming a surgeon in the navy, with which he served until about 1747. He resided in Edinburgh for the ten years from 1743, and during this period graduated M.D., was elected a Fellow of the College of Physicians, and published *A Treatise on the Scurvy*, the first written by a physician with experience at sea. Its importance may be gauged from the fact that in the then recent naval war scurvy had proved a more deadly enemy than the French and Spanish fleets. Lind's suggested remedy was the use of oranges, lemons, green food and onions, or, in their absence, of lemon juice. In 1757 he published *An Essay on the most effectual means of preserving the Health of Seamen in the Royal Navy* and a year later was appointed physician at Haslar. He contributed papers on fevers and infection in the Philosophical and Medical Society of Edinburgh, described a simple method of supplying ships with fresh water by distillation, following his discovery that the steam from salt water was fresh to the Royal Society in London in 1762, and six years later published *An Essay on Diseases Incidental to Europeans in Hot Climates*, which like his treatise on scurvy attracted notice throughout Europe. It is interesting to recall as illustrating the versatility of the medical profession that a contemporary of Lind's of the same name born in Scotland twenty years after him—and like him an M.D. of Edinburgh and a Fellow of the College of Physicians in that city—served as a surgeon with the East India Company, visiting China in 1766. This second James Lind afterwards published a *Treatise on the Fever of 1762 at Bengal*, became physician to the royal household at Windsor and a Fellow of the Royal Society of London and was an intimate friend of Shelley. He achieved some distinction also in the fields of astronomy, meteorology and geography, and took part in an expedition to Iceland.

DEATHS IN THE SERVICES

Brigade Surgeon Lieut. Colonel James Arnott, Bombay Medical Service (retired), died at Wyseley House, Kirtlebridge, Dumfriesshire, on August 18th, aged 83. He was born in 1845, and educated at Glasgow, where he graduated as M.D. and C.M. in 1866, and entered the I.M.S. as assistant surgeon on April 1st, 1867, attaining the rank of brigade surgeon in 1891, and retiring in 1908. He served in the Abyssinian campaign of 1867-68, receiving the medal and in the Afghan war of 1879-81, when he took part in the defence of Kandahar, the sortie of Dih Khoja and the battle of Kandahar. He was mentioned in dispatches in the *London Gazette* of December 3rd, 1880, and received the medal with a clasp. In 1896 he was granted a good service pension and at the time of his death had drawn such a pension longer than any other officer in the Indian army except one. For fifteen years after his retirement he was medical adviser to the Colonial Office for Scotland and he had served on the board of governors of the Simpson Memorial Hospital and the Victoria Hospital for Consumptives in Edinburgh. He leaves a widow, one son (who is a major in a Gurkha regiment) and three daughters. Lieut. Colonel Arnott came of a family which had been settled in Dumfriesshire and around Ecclefechan for nearly two centuries and which had given several medical officers to the East India Company's service. His father Surgeon John Arnott entered the Bengal service in 1837 and died while still comparatively young in 1845. His uncle Francis Shortt Arnott, entered the Bombay service in 1829 and rose to be inspector general, after serving in the Punjab war of 1848-49, in the siege of

Multan and at the battle of Gujrat, and in the Indian mutiny of 1857-58, in Central India, and the long campaign in pursuit of Tantia Topi. Another James Arnott, of the previous generation was in the St. Helena Medical Service, where he was superintending surgeon, and retired in 1835 after the company handed over the island of St. Helena to the Crown. He was said to have taken part in, or been present at, the post mortem examination of Napoleon, and lived till 1883.

Colonel John Herbert Whitehead, D.S.O., formerly of the R.A.M.C., died in Brompton Hospital, London, after an operation, on July 11th, aged 58. He was born at Addiscombe on September 30th, 1869, educated at Charing Cross Hospital, and took the M.R.C.S. and L.R.C.P. Lond. in 1893. After serving as house surgeon and house physician at Charing Cross, he entered the army as surgeon lieutenant on January 29th, 1895, but resigned his commission in the following year, on June 17th, 1896. He then went to South Africa and settled in practice at Johannesburg. On the outbreak of the Boer war he was ordered to join the Boer army or clear out of the country. He chose the latter course, and made his way to Ladysmith, arriving there in the last train which got through before the siege. He took service with the British troops as a civil surgeon, and served throughout the siege of Ladysmith, and until peace was made in 1902. He then joined Baden Powell's police as medical officer. When that force was disbanded he was stationed at Harrismith in the Orange River Colony and started in practice in that town, also going in for municipal work and being elected mayor. When the recent great war began in 1914 Harrismith was occupied by the rebel forces. He escaped, joined Botha's troops, and served throughout the suppression of the rebellion and the conquest of German South West Africa. He was prevented by illness from accompanying the South African contingent to Egypt and Europe and on his recovery went to German East Africa in command of a field ambulance, and for his services in that campaign received the D.S.O., subsequently serving as A.D.M.S. at Dar es Salaam and during the demobilization as A.D.M.S. at Durban. After the war he bought a farm at Plains Natal, and settled there practising his profession and farming. In 1900 he married Maude Kathleen Love, who had served as a nurse with him on the hospital ship *Alcoa*, and leaves a widow and two daughters.

Lieut. Colonel Manmatha Nath Chaudhuri, Indian Medical Service (retired), died at Mussorie in the United Provinces, India, on June 30th, aged 56. He was born on July 26th, 1871, and educated at the Calcutta Medical College and at Edinburgh University, where he graduated as M.B. and C.M. in 1897. Entering the I.M.S. as lieutenant on July 27th, 1899, he became lieutenant colonel after twenty years' service and retired on January 27th, 1927. During the recent war he served in Mesopotamia, and afterwards in Waziristan, on the North West Frontier, in 1919-20, and was twice mentioned in dispatches—in the *London Gazette* of August 15th, 1917, and of June 10th, 1921. Most of his service was spent in civil employment in the Madras Presidency, where before his retirement, he held the posts of professor of pathology in the Madras Medical College and superintendent of the Government General Hospital, Madras.

Lieut. Colonel Jarlath French Mullen, Bengal Medical Service (retired), died in Ireland on June 4th, aged 72. He was born in 1855, the fourth son of Lawrence Mullen of Tuam and educated at Queen's College, Galway, graduating M.D. and M.Ch. of the Queen's University, Ireland, in 1873, when he was only 17. He entered the Colonial Service in 1874, and served as a district surgeon in Jamaica for three years, and in 1877 he entered the Army Medical Department, passing in. In 1877 he entered the Netley course in January, 1878, but resigned after the Netley course in March, 1878, again. He entered the I.M.S. as surgeon on March 30th, 1878, again, passing in first, attained the rank of lieutenant colonel after twenty years' service, and retired in 1906. His whole service was spent in civil employment in Bengal, where he held the posts of civil surgeon of Rajshahi and Bardwan successively for many years during the latter half of his service. He was the author of two books of verse published under the pseudonym of Jahraith—*Eastern Sonnets* (1903), and *White Nights* (1905). Jarlath French Mullen was the youngest of four brothers, all of whom entered the public medical services. The eldest, St. Lawrence, was a staff surgeon in the navy. After his retirement he contested South Dublin without success as a Parnellite in 1892. The second and third brothers entered in the Bengal Medical Service. Thomas French Mullen entered in 1866, retired in 1896 and died two months later. The third, Douglas French Mullen, entered in 1877, retired in 1912 and died in 1920. These two both spent their service in Indian native States, under the Foreign Department. All four brothers entered the services under the name of Mullen, and added French to their names in 1890.

Obituary

ROBERT KNOX, M.D., M.R.C.P.,
D.M.R.E. M.I.F.F.,

Honorary Consulting Radiologist Queen Alexandra Hospital,
Millbank, Director of the Electrical and Radio-Therapeutical
Department of the Cancer Hospital

His untimely death, on September 21st, of Dr Robert Knox, in his sixty-first year, inflicts a heavy loss on British radiology. Knox was in the very front rank of his profession, and had come to occupy a unique position in the esteem and affection of x-ray workers, both in this country and abroad. Few men have held higher ideals and so unflinchingly endeavoured to live up to them.

Robert Knox was born in Leith, and received his medical education at Edinburgh and Guy's Hospital. He graduated M.B., C.M.D. in 1892, and proceeded M.D. five years later. In 1898 he obtained the diplomas M.R.C.S., L.R.C.P., the M.R.C.P. in 1926, and the D.M.R.E. Camb. in 1925. He settled in Highgate in 1894, and by sheer hard work and ability built up a large and successful practice. During that time he took an interest in local affairs and served on the Hornsey Borough Council, where his medical knowledge proved of great advantage to the community. He received the appointment of clinical assistant in the pathological department at the Royal Northern Hospital, where he became associated with Sir Thomas Horder.

Knox's foresight stood him in good stead when the x-rays were discovered. He at once took up the study of radiology, and later proceeded, while still in general practice, to establish himself in Harley Street as a consultant in this science. Presently he devoted himself wholly to the subject. His name became associated with an immense ability for taking pains, and this, coupled with a shrewd intelligence and a patent sincerity, brought him among the acknowledged leaders of his profession. His gentle, unassuming, and kindly ways inspired the confidence of his patients and endeared him to his colleagues.

Knox held for many years the directorship of the electrical and radiotherapeutic department at the Cancer Hospital in the Fulham Road, and here he undertook work on the treatment of cancer by x-rays and radium which earned for him an international reputation. As recently as last July he was paid the signal compliment of being invited to give an address on the subject at the International Congress of Radiology at Stockholm, he had laid his plans at the hospital for a team attack on the question during the coming year. During his career Knox was also associated with King's College Hospital, the Royal Northern Hospital, the Queen Alexandra Military Hospital, Millbank, and the Chelsea Hospital for Women.

Apart from his hospital and consulting practice, Knox worked unceasingly and ungrudgingly for British radiology, and did not spare himself in its service. His essential fairness and unselfishness, his freedom from prejudices, his wise counsel and his gifts as a conciliator found great scope on councils and committees. He was a past-president of the Röntgen Society and of the Electro-therapeutics Section of the Royal Society of Medicine. He played a leading part in the formation of the British Institute of Radiology, was first chairman of its management committee, and vice-president at the time of his death. As far as the Institute is concerned his loss is well nigh

irreparable. Knox was editor of the *British Journal of Radiology* for more than thirteen years, and his well-known book, *Radiography and Radiotherapeutics*, brought him great distinction. Part I of the fourth edition was reviewed in the *British Medical Journal* on March 8th, 1924 (p. 429).

He was a member of the War Office X-Ray Advisory Committee, of the X-Ray and Radium Protection Committee, of the Council of the Imperial Cancer Campaign, of the Radiology Committee of the Medical Research Council, and many others. He had much to do with the establishment of the diploma in radiology at the University of Cambridge, and he was one of the founders of the Society of Radiographers. He examined for the diplomas in radiology at Cambridge and Liverpool. It is known that the International Congress of Radiology owes its origin mainly to his vision and pertinacity. He was chairman of committee at the first congress in London three years ago. He was elected a member of the Institution of Electrical Engineers, and an honorary member of the

American Roentgen Ray Society, of the American College of Radiology, and of the Scandinavian Röntgen Ray Society. He found time also for work in connexion with the British Medical Association. He was secretary of the Section of Electro-therapeutics at the Annual Meeting in 1912 at Liverpool, vice-president of this Section at the Annual Meeting in 1920 at Cambridge, and president of the Section of Radiology and Electrotherapeutics at the Annual Meeting in 1921 at Newcastle-on-Tyne. Knox has left a lasting name in the science he loved so well, and there are many who not only lament the loss to British radiology, but grieve at heart at the taking away of a loyal friend and one who always lifted his eyes to the hills.

G. W. C. K.

Mr C. THURSTON HOLLAND, Ch.M., F.R.C.S., lecturer in radiology in the University of Liverpool, writes:

My acquaintance with Robert Knox began about twenty-three years ago. It began radio-

logically. I happened to see some very beautiful radiographs which were taken at a time when it was not so easy to get good results as it is now. I asked who took them, and then paid a visit to the Northern Hospital at Highgate to find a youngish, very reserved, very enthusiastic man in charge of an x-ray department which, in those days, was turning out better work than that produced in most hospitals. Knox was one of the most reserved of men, he did not make friends easily, but if once you penetrated his armour you found, hidden by this reserve, a most lovable man and a most storied friend. Happy in his home life, happy in his wife and his children, his work was at the same time his only hobby. The amount of work he did was stupendous, and it was all done in the most thorough manner. Knox was fortunate in that he very early on became a good pathologist, this knowledge of pathology did him good service when he took up x-ray work, and was one of the things which made his opinion of such great value.

His place in British radiology will not be easy to fill. Apart from the splendid editorship of the *British Journal of Radiology* for so many years, there was no movement for the advance of radiology in which he was not one of the prime movers. In his work for the British Institute of Radiology, the Röntgen Society, the Electro-therapeutics Section of the Royal Society of Medicine, on the

ROBERT KNOX, M.D.

Protection Committee, and for various other things he never spared himself, his time, or his money. It may be added that he was largely responsible for the building of the Edinburgh X-ray Department. Probably the most valuable bit of work he ever did was initiating the first International Congress on Radiology in London in 1925. It is not too much to say that this congress would never have been held except for Knox. He insisted, and eventually induced all British radiologists to support him. The congress was an outstanding and brilliant success, and it owed more to him than to anyone else. He managed to attend the second congress in Stockholm this year, but, although he was able to read a paper there on therapy, it was obvious to all his friends that he was seriously ill, and that it was only his indomitable will which had carried him through.

Dr A F BUNCLAY, lecturer in radiology in the University of Manchester, writes

There is not a radiologist in this country who will not feel the loss of Robert Knox, that quiet, wise counsellor, that bearer of grievances, that man who could wait and wait till passion had gone and reason could have its say. His work for radiology, and for every man associated with radiology, was his mission in life and to this end he gave of himself unstintingly seven days a week. Waking and sleeping, it was radiology in one form or another that was in his mind, and more particularly in these last few years when he spent so much thought on radiology in relation to cancer. What a willing horse he was! If there was a job to be done he would rather do it himself than worry others into doing work which was obviously theirs, not his, to undertake. If he had a fault it was that of undertaking too much, yet his accomplishment was such that he managed somehow to keep up with all the varied interests with which his name is so closely associated. Yes, Robert Knox will be missed, sadly missed, but he has done a great work and we must be thankful for it.

Dr G B BYTEN, past-president of the Röntgen Society, writes

Dr Robert Knox at the Royal Northern Hospital was one of the first to produce x-rays by employing the alternating current from the mains. He followed Dr Low as honorary secretary of the Röntgen Society, helped to found the British Association for the Advancement of Radiology and Physiotherapy, and, with Sir Archibald Reid, established the British Institute of Radiology. He was also prominently associated with the amalgamation of the Röntgen Society and the British Institute of Radiology. He was a ruling, if not the ruling, spirit in both these societies, and in the Electro-therapeutic Section of the Royal Society of Medicine. His colleagues quickly learnt to appreciate him for his breadth of vision, thoroughness, and balance, we all came to love this very quiet, modest, and efficient man. He brought to bear on every problem, whether clinical or of policy, a kindly dignity which evoked calmness and good results. Abroad he was probably the best known British radiologist, and he will be greatly missed.

Dr ARCHIBALD DUNBAR WALKER, who died at his residence in Hampstead on September 21st, where he had been living since his retirement, had spent nearly forty-five years in practice in London. The son of a surgeon in the East India Company's service, he was born in India in 1847. He received his medical education at the University of Edinburgh, graduating M.B., Ch.B. in 1868, and proceeding M.D. in 1871, having obtained the diploma M.R.C.S. Eng. in 1870. After some years as a medical missionary in Palestine, he commenced practice in London, where he spent forty-three years in the Ladbroke Grove and Notting Hill districts. He was a Fellow of the Royal Society of Medicine and a member of the Harveian Society, and also, during his active professional life, a member of the British Medical Association. Dr Walker was the author of several books, including *Egypt as a Health Resort* and *The Parent's Medical Note Book*, and several contributions from his pen appeared in the *British Medical Journal*

almost fifty years ago. His sister, Dr Ellen Walker Dunbar (who assumed the name Dunbar in 1874) died in August, 1925, in her eightieth year at Clifton, Bristol, where, in spite of her age, she was still engaged in practice, she was among the pioneer medical women in this country and was practising so long ago as 1873. Dr Walker's eldest son, Lieut.-Colonel N. Dunbar Walker, R.A.M.C., has carried the family connexion with the medical profession into the third generation.

The following well-known foreign medical men have recently died: Professor CHARLES ERNEST FIEBIGER of Liège, formerly president of the Belgian Royal Academy of Medicine, and one of the most eminent savants in Belgium, aged 76; Dr A. RUVULT, formerly president of the French society of laryngology, and the author of several articles on diseases of the throat, Professor SIDENMANN, a Basle laryngologist, aged 76; Dr JEAN JACQUES MATIGNON of Clutel Guyon, formerly medical adviser to the French Legation at Peking where he distinguished himself during the siege by the Boxers, and the author of several works on life in China, aged 61; Dr FROMASSET, a Bordeaux ophthalmologist, Colonel CARL BOHNY of Basle, senior medical officer of the Red Cross, Professor PAUL KUCERA, director of the Prague Institute of Hygiene, Professor L. BAUTH, a Berlin physiologist aged 65, Dr JOSEPH MERCKX, a Brussels oto-rhino-laryngologist, Professor O. KILIANI, formerly professor of surgery at New York, Professor G. ROSSIER, a Lausanne gynaecologist, aged 65, Professor EMIL FROMM, director of the Institute of Medical Chemistry, and Professor L. BUDENSTEIN, an authority on school hygiene at Vienna.

Medical News.

SIR WILLIAM WATSON CHEYNE, Bt, F.R.C.S., will preside at the opening of the winter session at King's College Hospital Medical School, Denmark Hill, S.E., on Wednesday, October 3rd. Professor Ernest Barker will deliver the introductory address at 2.30 p.m.

THE winter session of the London (Royal Free Hospital) School of Medicine for Women opens on Monday, October 1st, at 3 p.m., when Dr Andrew Balfour, C.B., C.M.G., will give the introductory address on "The tropical field: its possibilities for medical women."

THE annual prize distribution at St. George's Hospital Medical School will be held in the board room of the hospital on Monday, October 1st, at 3 p.m., when the inaugural address, entitled "Hydrocephalus: a study in phylogeny and pathology," will be delivered by Sir John Bland Sutton, Bt, F.R.C.S. The annual dinner will be held the same evening at the Hyde Park Hotel at 7.15 for 7.45 p.m., when the chair will be taken by Dr W. S. Fox.

THE introductory address at the Royal Veterinary College, Great College Street, Camden Town, N.W., will be given by Sir Merrick R. Burrell, Bt, chairman of the General Purposes Committee of the Board of Governors, on Tuesday, October 2nd, at 3 p.m. The chair will be taken by Sir Archibald Weigall.

THE inaugural address at the opening of the eighty-seventh session of the School of Pharmacy of the Pharmaceutical Society of Great Britain will be given by Mr Reginald R. Bennett, B.Sc., F.I.C., chairman of the Pharmaceutical Conference, at 17, Bloomsbury Square, London, W.C., on Wednesday, October 3rd, at 3 p.m. The presentation of the Pereira Medal will take place on the same occasion.

THE Harben Lectures on studies in asthma and related diseases before the Royal Institute of Public Health will be given at 37, Russell Square, W.C.1, by Dr Arthur T. Henderson on October 23rd, 25th, and 30th, at 4 p.m. A course of lectures on industrial diseases will commence on October 17th at 4 p.m., when Dr E. Graham Little, M.P., will deal with the health of the medical practitioner.

At the meeting of the Royal Sanitary Institute to be held on Friday, October 5th, in the Town Hall, Lowestoft, a discussion on economy in refuse disposal will be opened by Mr S. W. Mohbs. The chair will be taken at 5 p.m. by Professor A. Bostock Hill, M.D.

SIR JOHN W. THOMSON WALKER, F.R.C.S., has been appointed a Deputy Lieutenant for the County of London.

From October 1st the administrative offices of the Medical Research Council, hitherto at York Buildings, Adolph, will be at 38, Old Queen Street, Westminster, S W 1 (Telephone Victoria 5327). The offices of the Industrial Fatigue Research Board will also be at the new address.

A COURSE of elementary lectures on infant care will be given by Dr Prudence Gaffikin, in the Lecture Hall, Carnegie House, 117, Piccadilly, W 1, on Thursdays from 7.30 to 8.30 p.m., from October 11th to December 13th.

A COURSE of post graduate lectures on nutrition intended for health visitors, nurses, midwives, and superintendents of infant welfare centres, will be given at the Infants Hospital, Vincent Square, Westminster S W, on Mondays, from October 8th to December 10th, from 6.30 to 7.30 p.m.

A NEW course of lecture demonstrations arranged by the South West London Post Graduate Association at the St James's Hospital, Ouseley Road, Balham S W 12 will begin on Wednesday, October 24th, at 4 p.m. when Professor H. H. Mottram will speak on the white and brown bread controversy. The lectures will be continued on succeeding Wednesdays, at the same hour, until December 4th.

The course of post graduate lectures at the Ancients Hospital, Manchester, for the session 1928-29 will open on Thursday, October 4th, at 4.15 p.m. The series consists of three lectures by Dr W. T. S. Reid on diseases of the sympathetic nervous system, to be given on October 4th, 11th, and 18th, two lectures by Mr. Diggle on ear, nose, and throat diseases on October 25th and November 1st and two lectures by Dr. Henshaw on November 8th and 15th, one on recent advances in medical and surgical antiseptics and the other on uric acid with special reference to laboratory aids to diagnosis. There is no fee for the course, to which medical practitioners and senior students are invited. Tea will be served each day at 4.45 p.m.

A THREE DAY post graduate course will commence at St Mary's Hospital, Paddington, on Saturday, October 6th, when the following subjects will be dealt with. At 11 a.m. Dr. I. G. Hald Miller will speak on the intestinal child, at 12 noon, Mr. William Wilcox on food poisoning and paratyphoid infections, at 2.15 p.m., Dr. A. H. H. Gossie on prognosis in heart disease, and at 3.15 p.m., Mr. R. M. Handfield Jones on recent advances in everyday surgery. On Sunday, October 7th, Mr. Aleck Bonrue will discuss at 10.15 a.m., the new ovarian hormones, at 11 a.m. Dr. C. M. Wilson will deal with some common difficulties in diagnosis, and at 12 noon Dr. Zachary Cope will give a demonstration of clinical cases and pathological specimens. On Monday, October 8th, the subjects to be dealt with include the use of radium in malignant disease, by Mr. Duncan C. L. Fitzwilliams, at 11.15, some surgical obsessions, by Professor C. A. Pannett, at noon, the nature and relief of some common gastric symptoms, by Dr. John Ryle, at 12.15 p.m. and at 3.15 p.m., some pitfalls in obstetrics, by Dr. T. G. Stevens. The meetings will be held in the library of the Medical School, and are open to all medical practitioners without fee.

THE Fellowship of Medicine and Post Graduate Medical Association announces that at the Prince of Wales's General Hospital, Tottenham, there will be an all day course in medicine, surgery, and the specialties from October 8th to 20th. During the same period the Chelsea Hospital for Women will hold a course in gynaecology. From October 8th to 27th there will be a special course at the Central London Throat, Nose and Ear Hospital, consisting of clinical, practical operative, and pathology sections. On Tuesdays and Thursdays in the four weeks from October 9th the Tropical Hospital will hold a course of clinical instruction in tropical diseases, and from October 15th to 27th the Hospital for Sick Children, Great Ormond Street, will provide a special morning course of children's diseases. Professor Louis Vellroy will give four lecture-demonstrations on ante-natal treatment at the Royal Free Hospital, beginning on Friday, October 26th. From October 29th to November 10th there will be a practitioners' course in medicine, surgery, and the specialties at the Hampstead General Hospital in the afternoons. In addition weekly clinical demonstrations at various hospitals, demonstrations on Wednesday afternoons at the Wellcome Museum of Medical Science, and a series of lectures on Mondays at 5 p.m. at the Medical Society, 11 Chandos Street W 1, have been arranged all being open to members of the medical profession without fee. Syllabuses of these and of all courses may be obtained from the Fellowship of Medicine, 1, Wimpole Street, W 1.

A POST GRADUATE course on rheumatism, including the etiology, pathology, differential diagnosis and surgical and orthopaedic treatment of chronic arthritis will be held at Aix in Chapelle from October 18th to 20th. The fee is £10. Further information can be obtained from the Rhonua Forschungs-Institut, Landesbad Aachen.

AMONG the speakers from foreign countries at the second International conference on light and heat in medicine, surgery, and public health, to be held in London from October 29th to November 1st, will be Dr. Franz Nagel, schmidt of Berlin, Professor Jeslonek of Giessen, who will contribute a paper on ultra violet therapy in dermatology, and Dr. Wilhelm Linskamp of Erlangen, who will speak on conservative treatment in gynaecology, with special reference to the use of light and heat. The chair, at the opening ceremony of the exhibition, will be taken by Dr. F. E. Fraenkel, M.P. The honorary organizing secretaries are Drs. W. Kerr Russell and R. King Brown.

At the recent Model Engineering Exhibition held in the Royal Horticultural Hall, Westminster, the Admiral Bacon cup for the best amateur work, and a silver medal, were awarded to Dr. C. Nepean Longridge for his working model of the Blue Funnel steamship *Verones*.

THE minutes of evidence taken by the Departmental Committee on Ethyl Petrol during the four public sessions held in April, May, and June have now been published, and are obtainable from H. M. Stationery Office (price 5s. 6d. net), they comprise the evidence heard prior to the preparation and issue of the interim report (Cmd. 3159), which was reviewed in the *Journal* of August 4th (p. 219). Among the witnesses examined were representatives of the manufacturers and importers of ethyl petrol, of the United States public health service, and of certain Government departments, including Dr. J. C. Bridge, of the Home Office, evidence was also given by Mr. William Pope, Professor H. B. Baker, Professor C. I. Finch, and Dr. Myci Coplans. Reports of the proceedings were published in the *Journal* after each meeting of the Committee, but the minutes of evidence now available give a much fuller account; they are accompanied by the memorandums submitted by various witnesses, and disclose many points of interest to those who are concerned with this problem.

MR. BERNHARD BARON has by deed transferred the sum of £575,000 10s. 9d. per cent Consolidated Loan to trustees for the foundation of a trust to be called "The Bernhard Baron Trust for Hospitals and Asylums for Orphans and Crippled Children." It is provided that during the next twenty years the total amount available for distribution shall be approximately the same each year, and the trustees shall in every year apply such part of the capital and income of the fund as they deem fit for the benefit of hospitals of various kinds and homes and institutions for the care of orphaned and crippled children. The money available is directed to be applied in the proportion of 75 per cent among Christian and non-Christian national hospitals, homes and asylums, and 25 per cent among similar institutions under Jewish control. The Marquess of Blandford is nominated chairman of the board of trustees, and the annual distribution will take place on December 5th of each year, which is the anniversary of the donor's birthday.

A REGISTERED medical practitioner named Joseph Randolph Morell MacKenzie appeared before Mr. Campion at the Tower Bridge Police Court, on September 17th, in answer to summonses under the Dangerous Drugs Act for failing to enter in a register particulars of various purchases of morphine sulphate. It was stated that when the summonses were served the defendant showed entries in a memorandum book relating to the purchases in question, admitting that they had been made after an inquiry had been started by the police. Mr. Davis, defending said the practice of medical men was extremely lax in these matters, and urged that the Act referred to supplying drugs and not to purchasing them, he added that the defendant did not realize what the regulations implied. The magistrate thought that doctors must be well aware of the import of the regulations. Answering questions, the defendant said that he had not kept a register for the past nine years, and that the Act did not apply in Northern Ireland where he had been. Mr. Howe, who represented the Director of Public Prosecutions mentioned that Dr. MacKenzie had been charged at Rumsate in April with stealing tablets of morphine sulphate and in June was sent to a home for drug addicts, until he could be certified as cured when he was released under the Probation Act. The defendant was remanded for three months on his own and one other surety in £50 each, a colleague promising to look after him.

ABOUT 250,000 cases of dengue are reported as having occurred in Greece in the course of three weeks.

DR. F. D. HERELLE of Paris, who is well known for his study of the bacteriophage, has been appointed professor of bacteriology at Yale University.

INSPECTOR G. F. FRAI DOPTER, the well known French epidemiologist, has been nominated director of the health service of the military government of Paris.

Letters, Notes, and Answers.

All communications in regard to editorial business should be addressed to **The EDITOR, British Medical Journal, British Medical Association House, Tavistock Square, W C 1**

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the **BRITISH MEDICAL JOURNAL** alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names not necessarily for publication.

Authors desiring REPRINTS of their articles published in the **BRITISH MEDICAL JOURNAL** must communicate with the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W C 1, on receipt of proofs.

All communications with reference to ADVERTISEMENTS as well as orders for copies of the **JOURNAL**, should be addressed to the Financial Secretary and Business Manager.

The **TELEPHONE NUMBERS** of the British Medical Association and the **BRITISH MEDICAL JOURNAL** are **MUSEUM 9861, 9862, 9863** and **9864** (internal exchange, four lines).

The **TELEGRAPHIC ADDRESSES** are

EDITOR of the **BRITISH MEDICAL JOURNAL**, *Atitology Westcott London*

FINANCIAL SECRETARY AND BUSINESS MANAGER

(Advertisements etc.) *Articulate Westcott London*

MEDICAL SECRETARY *Mediscera Westcott London*

The address of the Irish Office of the British Medical Association is 16 South Frederick Street, Dublin (telegrams *Bacillus Dublin* telephone 62550 Dublin), and of the Scottish Office, 7 Drumslough Gardens, Edinburgh (telegrams *Associate, Edinburgh*, telephone 24361 Edinburgh).

QUERIES AND ANSWERS

VISCERAL PAIN

"ANCEPS" writes: I shall be grateful for a reference to the latest views on the causation of visceral pain. I am acquainted with the theories of Mackenzie, Head, Sherrington and the later publications of Ryle and Morley. Both the latter appear to differ sharply in their opinions from the earlier writers mentioned. I would like, if possible, to obtain information, from both the sensory and motor aspects of the subject.

DERMATITIS EXFOLIATIVA.

Dr. F. H. B. NORRIS (Calcutta), replying to "W. M. B." (*British Medical Journal*, August 4th, p. 227) refers to a case of this condition cured by a course of injections of urea stibamine (*Indian Medical Gazette*, March, 1927). Equally good results followed this treatment in a second case.

VAGINISMUS

"E. A. C. H." writes: In answer to "C. A. E." inquiry about vaginismus (September 8th, p. 473), I had a very similar case, my attempt at the act proving extremely distressing. I advised coaculated vaseline (8 grains to the ounce), to be applied to the vulva a quarter of an hour before any act. I particularly advised for obvious reasons that emerging the clitoris should be avoided. The patient quite understood. My advice was apparently attended with success for it was not long after that I was glad to learn of conception, and in due course of the birth of a fine male child.

TREATMENT OF COLI BACILLURIA

"M. M. E." writes to suggest that "I. M. S.," whose inquiry appeared in the *Journal* of September 15th (p. 513), should try oystoparin (hexamine-sodium acetate) in doses of gr. j six times a day.

LETTERS, NOTES, ETC.

ENCEPHALO MYELITIS IN THE MIDLANDS

Dr. J. D. SLIGHT (honorary physician Leicester Royal Infirmary) writes: As I have not noticed any reference to the occurrence of nontyphoid encephalo-myelitis in the Midlands it seems to me that it may be of consequence to report that I have seen seven cases here since April. All the patients were adults, all were seriously affected, and none had been vaccinated recently.

SEA SICKNESS

Dr. T. GIBSON (Ontario) writes: Whatever be the true explanation of the cause of *mal de mer* the sickness must follow reflex disturbance of the vomiting centre which is supposed to be in close proximity to the sensory vagus nucleus. Some years ago I used a proprietary remedy, but I found the capsules were of very unequal potency. After one dose there was nausea and excessive dryness of mouth and throat so that speaking and swallowing were difficult while after another dose there might be very slight effect. Once or twice there was distinct interference with accommodation. It seemed obvious, therefore, that one of the belladonna group was the chief drug concerned. The danger of unequal dosage was perhaps illustrated by the experience of a patient of mine, who used the remedy on her own account, and had to undergo an operation for acute glaucoma on arriving at Liverpool. There was no doubt, however, that relief was obtained from the symptom of nausea. Since that time I have been in the habit of prescribing the following two

preparations in capsules for prospective transatlantic travellers: (1) hyoscine hydrobromide gr. 1/250, sacchar. lactis q.s., (2) chloroform gr. 1ij. One of each was taken on waking any time after 6 a.m. and half an hour before lunch and dinner. If mixed together these drugs liquefy and may escape from the capsule. It is important that the druggist should dispense the capsules in boxes of different shapes, so that the mistake of taking two of one sort, instead of one of each, may be more easily avoided. Hyoscine was preferred to atropine as being centrally more sedative. Chloroform was added as an adjunct because of its direct local sedative effect on the stomach. The *Extra Pharmacopoeia*, vol. 1 (p. 261), warns against giving more than gr. x of chloroform in one day. This drug has been much used to relieve sea sickness. My experience has been that this combination in the above dosage is safe, and in many cases acts well as a preventive. The last trial made of it was in the case of a lady who had never taken a train journey without great suffering from dizziness and nausea. During a four-day trip to Colorado, using the above prescription, she had a comfortable journey. Patients should be warned to use it with much caution and not to repeat a dose out of time unless the capsules should happen to be rejected quickly after being swallowed.

"AMBÓ" writes: Those of us who have experienced the pangs of sea sickness as well as the annoyance of the attacks of what is spoken of as *Ménière's disease* will agree that the combination of symptoms in both is the same. The attacks of *Ménière's disease* can be ward off or postponed by carefully attending to the hepatic function. This may be of interest in view of Mr. Paramore's statement on June 2nd (p. 959) that sea sickness is possibly attributable to disturbance of the hepatic circulation.

ABNORMAL PIGMENTATION OF THE SCALP

Dr. E. A. COCKAYNE (London, W 1) writes: Several examples of this rare condition have been recorded in this *Journal* during the present year, and one is attending my out-patient department. The boy, aged 7 years, has a patch of black hair about 3 in. by 1 in., on the right parietal region. The black hair is sharply demarcated from the rest of his hair, which is light brown, in texture it is like the brown hair and the skin on which it is growing is pigmented and normal in all respects. His eyes are grey. The surname Whitelocks was given to a family many of whose members had a white patch on the scalp. Did the name Blacklock originate in a similar way?

THE KEEPING PROPERTIES OF FOOD

"M. D." writes: I recently celebrated my silver wedding. My wife and family and I partook of small portions from a slice of the original wedding cake which I had put into a tin twenty-five years ago the lid of which I had soldered up. Except for a slightly rancid taste and odour it was in wonderful preservation, and still retained the ordinary flavour of such cake. Curiously enough no part of the tin's contents was recognizable as sugar, icing or almond. I may add that the Lister Institute was good enough to report on it before we tasted it. It was bacteriologically sterile apparently. No one of us was upset by the small portions we consumed. I possess another tin with a piece of the same original cake. The intention is to keep it in case a golden wedding anniversary is ever reached.

A SWALLOWED BROOCH

Dr. O. M. ANDERSON (London S W 10) writes: The following incident is unique in my experience and I thought of sufficient interest to report. Three months ago an infant aged 6 months was thought to have swallowed a safety pin brooch, as it was missed at that time. The parents did nothing in the matter as the child developed no symptoms. Two days ago the brooch was passed per anum with a rather constipated stool which the nurse happened to examine rather carefully. The brooch is 2½ in. long, was open and a pearl which was attached had disappeared, leaving a rough facet, which projected above the surface.

"THE CLUB SURGEON"

Miss M. L. SPACKMAN (Chiltheroe, Lancashire) writes: Readers of the late Dr. Arthur Manknell's address on the British Medical Association published in the *Supplement* of September 8th may be interested to know that Professor Henry Morley wrote a graphic account of "club work" in an article, "The club surgeon" which appeared in *Household Words* during the 1880s. It is reprinted along with articles describing Professor Morley's experiences as a practitioner, in *Early Papers—and Some Memories* published in 1891 by Routledge and Sons.

A DISCLAIMER

Dr. JOHN YEARSLEY (Bournemouth) writes: My attention has been called to an article purporting to be a short account of myself, my activities, professional qualifications, etc., in a small periodical published by a local cinema. This article was inserted without my knowledge and consent, and has caused me great annoyance.

VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals will be found at pages 43, 44, 45, 48, 49, and 50 of our advertisement columns and advertisements as to partnerships, assistantships, and locum tenencies at pages 46 and 47.

A short summary of vacant posts notified in the advertisement columns appears in the *Supplement* at page 147.

Remarks

OF

THE TREATMENT OF GANGRENE.*

BY

W. SAMPSON HANDMAN, M.S., F.R.C.S.,
Surgeon to the Middlesex Hospital

From the fact that Professor Leriche was originally asked to open this discussion, and that, failing him, I have been asked to do so, I gather that the interest of the occasion is expected to centre on the more recent methods of vasomotor surgery in relation to gangrene. I may be absolved therefore, in opening the discussion, from attempting a general survey of the whole subject, and my remarks must not be taken as limiting the scope of the subsequent discussion.

A word of gratitude to the physicians is appropriate, and especially to Dr Banting, for the gift of insulin, which has entirely changed the outlook in cases of amputation for diabetic gangrene and in other operations upon diabetics. In such cases the co-operation of a physician is now essential, and when the urine has been rendered sugar-free by insulin the surgeon can intervene almost as confidently as in the non-diabetic, such at any rate is my experience.

Vasomotor Surgery of Gangrene

The surgery of the sympathetic owes its modern development to the observation of Claude Bernard that section of the cervical sympathetic causes dilatation of the vessels of the head and dilatation of the pupil on the side of the operation. Waller showed that stimulation of the peripheral or upper end caused constriction of the vessels and contraction of the pupil. Thus the motor action of the sympathetic upon unstriated muscle was clearly demonstrated, and the surgeon was presented with the key of the arterial sluices, and given the power of flooding areas of low nutrition with reviving blood.

At first the attack was made chiefly on the main sympathetic chain, or upon the nerves passing to this chain from the special nerves—a dangerous, difficult, and uncertain field of surgical work.

Jaboulay and Leriche transferred their attention to the peripheral parts of the sympathetic nerves which, as Jaboulay knew in 1896, run along the main arteries of the limbs on their way to the arterioles.

Though the modern surgery of the sympathetic is mainly a French structure, there are embedded in its foundations some forgotten stones of British origin. I find that John Hunter did an experimental decortication of a dog's artery to find whether defect or injury of the external coat will produce an aneurysm. Hunter says:

"I dissected the carotid artery of a dog taking off carefully the external coat until I could almost see the blood through the internal one. I then left the dog and his artery to themselves at the end of three weeks killed the dog, when I found the surrounding parts had consolidated themselves to the artery, rendering it stronger in this part than it was before."

Lord Lister showed in 1858 that the destruction of the posterior half of the spinal cord in the frog produced permanent paralysis of the arteries of the hind limb. Preservation of any segment, however small, of the posterior half of the cord allowed the arteries to recover their tone. He also showed that even after division of all the soft parts of the hind limb except the main artery and vein, the arteries of the distal portion, after initial paralysis, soon recovered their contractile power. The

nervous filaments concerned must, as Lister pointed out, run along the main artery or vein, or, less probably, through the bone.

I wrote to the late Professor Bayliss and drew his attention to Lister's crucial experiment showing that the vasomotor nerve supply ran along the main blood vessels. He replied saying that the recovery of tone in Lister's experiment, where, as you remember, all the soft parts were divided except the main artery and vein, might be ascribed to a natural tendency on the part of unstriated muscle removed from nervous control to go into spasm. This interpretation is negatived, it seems to me, by Lister's other experiment showing permanent loss of vascular control in the hind limb after destruction of the posterior half of the spinal cord. In my opinion Lister's experiments demonstrate that nerve fibres running along the main vessels are an essential factor in the vasomotor control of the arterioles of the limbs, and vasomotor surgery has thus an experimental basis.

Jaboulay, about 1906, endeavoured to produce vasodilatation of the foot in perforating ulcer by denuding the femoral artery and tearing away the small nerve twigs which, in the region operated upon, were found passing to the artery from adjacent nerves. Leriche, in order to interrupt more completely the sympathetic filaments removed the outer coat of the artery for a considerable length—a true decortication of the artery, such as Hunter had experimentally practised—and he called this operation sympathetomy. To avoid confusion it is best to describe Leriche's operation as arterial sympathetomy.

Leriche thus describes his operation:

"The technique is to isolate the artery on [?] for 8 to 10 cm. to fix the vascular sheath after dividing to hold one part with a forceps and dissect off the cellular tissue either with knife or cannula round until there has been effected complete denudation of the vessel, which becomes greatly reduced in size. This brings no injury to the arterial wall. I verified this fact twice at four and eight months interval."

Leriche has had successes from sympathetomy in the following conditions: (1) causalgia after war wounds, (2) certain painful crises preceding gangrene caused by obliterative endarteritis, (3) "painful acroparaesthetic syndromes consecutive to bruise of finger, to wounds of hand, palm, or foot-sole", (4) in Raynaud's disease, (5) sometimes in cases of painful stump, (6) in muscular spasm secondary to war wounds, (7) in trophoedema, (8) in trophic ulcers, but here the result may be temporary.

Effects of Leriche's Operation

Leriche finds that as soon as the adventitia is pinched a contraction of the vessel occurs, its pulsation stops, and its size diminishes. If the cellular layer (presumably the tunica adventitia) is actually excised, the artery shrinks still more, to one-third or one-fourth only of its normal size. The contraction affects only that portion of the artery which is injured by the operation. It usually causes the pulse to disappear, but does not altogether interrupt the circulation. For some hours pulsation is imperceptible or feeble and the limb is colder than its fellow by 3 or 4 degrees Centigrade—a very serious consideration in cases of actual or threatened gangrene. After three to fifteen hours entirely different symptoms supervene—namely, (1) an elevation of local temperature, amounting to 2 or 3 degrees in the affected limb, accompanied by a subjective sensation of heat, (2) an elevation of arterial pressure up to 4 mg. in the affected limb as compared with the opposite limb, (3) an increased amplitude of the pulse, as shown by sphygmographic tracings.

It is important to notice that after periarterial sympathetomy this vaso-dilator reaction is transitory. It diminishes about the fifth or sixth day and disappears in three to four weeks.

* Made in opening a discussion in the Section of Surgery at the Annual Meeting of the British Medical Association, Cardiff, 1928.

It will be noted that Leriche does not recommend his operation for actual senile gangrene, and Matthöy-Cornat gives as definite contraindications for sympathectomy (a) the circulatory insufficiencies of generalized senile arteriosclerosis, with or without gangrene, (b) arterial thrombosis and obliterations. He points out the danger, in gangrenous or pre-gangrenous conditions, of the ischaemic period of lowered circulation which follows Leriche's operation and the risk of attempting decortication on an atheromatous artery. Matthöy-Cornat devotes special chapters to the dangers and accidents of sympathectomy, with 6 deaths and 40 accidents in 500 cases. Among the accidents are rupture of venous plexuses, tearing off branches of the artery, wounds or lateral perforation of the artery, sometimes necessitating ligature of the vessel, total rupture of the artery, secondary haemorrhage, thrombosis of the artery, and replacement of dry gangrene by rapidly spreading moist gangrene.

Leriche, on the other hand, holds that sympathectomy may render durable service in senile arteritis if used with discretion. He thinks it indicated in the severe premonitory pains of gangrene except when there are attacks of "paradoxical" vaso-dilatation with heat of the foot. The operative outlook is, however, poorer in presence of habitual cyanosis, diffuse oedema, or neuritic pains than when the attacks are of vaso-constrictor type. Tissue infections contraindicate the operation. For incipient gangrene it is indicated if examination shows that the arteries are still dilatable. If they appear obliterated the operation is only justifiable to prepare the way for a low amputation close to the gangrenous area. Sympathectomy, he thinks, is useless for intermittent claudication upon present evidence. If, upon exposure, the artery is found friable and "malacique" he recommends my method of alcohol injection. If it is transformed into a hard impermeable cord the artery should be resected to interrupt the sympathetic fibres. For the gangrene of young subjects he places more hope for the future in internal secretion therapeutics than in surgical measures, which can only have a temporary effect.

Leriche suggests that in order to minimize the risk of gangrene in cases where the main artery of a limb has to be ligatured, as for aneurysm, the artery instead of being simply tied should be divided between two ligatures. He states that whereas simple ligation is followed by dangerous vaso-constriction lasting some hours, resection of the artery produces immediate and lasting vaso-dilatation. No doubt the same effect could be obtained by a combination of alcohol injection with simple ligation.

I must now call your attention to the method of alcohol injection, which I believe to be a definite advance upon Leriche's operation. I claim for it that it is able in certain cases to avert threatened gangrene or to arrest the spread of senile gangrene already present and to avert the necessity of amputation. In other cases it permits a low amputation to be used instead of a high one.

The technique of periarterial injection is not difficult, though it requires care and delicacy. The femoral artery in Hunter's canal is exposed as for ligature for a length of one or two inches. With the finest obtainable hypodermic needle 2 to 3 minims of alcohol are injected at four points spaced out round the calibre of the artery. The needle is introduced obliquely and nearly parallel with the length of the artery. The artery may be partially rotated to make the posterior injections. On one occasion I punctured the artery and injected alcohol into its lumen. This was shown by bleeding on withdrawal of the needle. The puncture sealed under sponge pressure and no ill effect followed. When the injection is complete a whitish band, perhaps half an inch wide, should be seen round the artery, but no constriction takes place. The wound is closed.

Effects of Alcohol Injection

In successful cases the vaso-dilatation produced by alcohol injection is immediate. There is no initial period of vaso-constriction with slackness or absence of the distal pulse lasting for some hours, such as follows sympathectomy. The cold foot may become obviously warmer than the

sound one even before the patient is out of the operating theatre. This fact alone, especially in cases of threatened gangrene, gives the method a decisive advantage over sympathectomy. But this is not the only advantage. Whereas the effect of sympathectomy, according to Leriche, passes off within about five weeks the vaso-dilatation following alcohol injection may last for a year or more. These clinical differences may be connected with the absence in alcohol injection of the local contraction of the artery seen in sympathectomy.

Criticisms

The method of alcohol injection is open to many criticisms. It is admittedly uncertain in its results. Sometimes no alteration in the circulation or surface temperature of the limb can be detected. It appears probable that there are anatomical differences in the distribution of the vasomotor nerves, and that while they sometimes join the artery high up so that they are amenable to alcohol injection of the femoral, in other cases they join it below the level of the injection. In senile cases organic changes of the artery may have made such progress that the muscular mechanism of the vessels may be entirely functionless or the main arteries may be thrombosed. It is to be specially noted, however, that some cases with advanced organic changes in the vessels, and no pulse to be felt in the limb, may nevertheless be strikingly benefited. Moreover, in thrombosis of the main artery the operation may assist in opening up the collateral circulation. But it must be admitted that it is at present impossible to make a proper selection of cases.

What are the indications for alcohol injection? They are not yet defined, and a process which appears to be so safe leads itself to the method of trial. My experience would lead me to recommend it strongly in cases of threatened or incipient senile gangrene of a lower limb. It should, if possible, be applied in the prodromal stage, where severe pain and pallor and coldness of the foot are the principal symptoms, and before actual gangrene has occurred. Extensive gangrene reaching to the leg is a contraindication unless alcohol injection is followed by an immediate low amputation, since, as I have shown, the increased blood supply may lead to fatal toxic absorption. If the foot above the dead area is congested, and warmer than the sound foot, the operation is contra-indicated. In such cases there is probably a septic infection of the tissues, associated with already existing vaso-dilatation.

Alcohol injection appears to be useless in Buerger's disease, and of doubtful value in Raynaud's disease. I have not yet tried it for chronic or perforating ulcer of the foot or for painful or ulcerated stumps.

In conclusion I would say that the surgery of the sympathetic is yet in its infancy, and that it requires for its development a further study of the sympathetic system by anatomists and physiologists and of arterial disease by the pathologists. Many obscurities still remain. Leriche's operation has been justified by a number of brilliant successes in other conditions. Leriche himself does not recommend it for incipient or actual gangrene. Though some surgeons continue to use it for actual or threatened gangrene, I believe that it will be replaced by the method of alcohol injection, which secures the same result in a simpler and safer way without risk to the integrity of the artery, without initial vaso-constriction, and with more permanent vaso-dilatation. For these reasons I think alcohol injection is not a mere technical variation of Leriche's method, but a distinct advance upon it, and that, particularly in senile gangrene, it is the vasomotor operation of choice.

While vasomotor methods can be applied successfully in the early stage of gangrene to limit its spread and to restore the vitality of dying tissue, they find their main field of application in an earlier stage before gangrene has actually begun. A serious additional responsibility is thus placed upon the medical man to whom complaint is first made of symptoms of arterial dystrophy likely to end in gangrene. Upon him it devolves to allow vasomotor surgery a fair field for its attempts to avert the loss of a limb.

THE FALLACY OF X RAYS IN ABDOMINAL DIAGNOSIS*

BY

HIRSHI RT J. PATTERSON, C.B.I., M.Chir.,
M.A., M.D. CANTAB. 1.R.C.S.,Hunterian Professor of Surgery Royal College of Surgeons
of England

We flatter ourselves that we live in the age of scientific medicine. No one would wish to belittle the value of scientific methods, but there is a real danger that in our quest for the precise and the scientific we are tending to neglect the practice of medicine. Notwithstanding all the aids which science can give there still remains the personal factor—call it judgement, intuition, or what you will, medicine is still essentially an art. In recent years laboratory methods have been developed to such an extent, and their precision is so alluring, that we are apt to forget the simple truth that, medicine being an art, a diagnosis cannot be made in a test tube.

The advent and evolution of the x rays has added a valuable diagnostic method to the surgeon's armamentarium, but it is by no means an infallible one. After all, radiology is but an aid to diagnosis and not a substitute for clinical observation. We are far too ready to accept as gospel the diagnoses which are made for us in the laboratory or in the x ray room, sometimes, I fear, to the exclusion of clinical examination. In cases of fracture it is not unknown for a house surgeon to say, quite openly and without blushing, that he has not made a diagnosis, but has sent the patient to the radiologist for a report. This is quite wrong. We should make our own diagnosis before we call in the help of the radiologist to confirm it. We should not be slaves to the laboratory. Laboratory investigations are good servants but bad masters. As the Americans have pithily put it, "Don't let the radiologist wag your tail."

In connexion with radiology, especially in abdominal work, there are two great fallacies of which we must beware. First, the fallacy that radiology can be a substitute for a careful and thorough clinical examination. In diseases such as gastric and duodenal ulcer, in which physical signs are often absent, it is very tempting to have a radiograph taken without obtaining the detailed and exact history of the case, which is so essential for diagnosis. Secondly, the assumption that there is such a thing as a radiological diagnosis is a fallacy. A radiological diagnosis, as such, does not exist. Apart from the clinical signs and symptoms a proper diagnosis is impossible. Radiology is not a final court of appeal, it is part only of the considerations on which the diagnosis is based. The radiological findings should fit in with, and agree with, the clinical signs and symptoms. If they do not do so, we had better start afresh and review the clinical findings to see if we have missed something or overrated the importance of some sign or symptom.

We should beware of regarding the radiologist's report as infallible. We are apt to be misled by the saying that the "camera cannot lie." Even if this were true, we must remember that a radiograph is not a photograph, but a shadow, and may be distorted by the angle of exposure of the film. Further, the shadows have to be read in the light of past experience, and there is ample scope for error in the interpretation thereof. The radiologist may guess, draw inference, not warranted by what

he has actually seen, and then jump to conclusions which may be misleading, and may suggest an erroneous diagnosis.

The chief fallacies which he is in wait for the surgeon may be grouped under four heads:

- 1 Fallacies incidental to x rays
- 2 Fallacies due to technique
- 3 Fallacies of misdirection
- 4 Fallacies of interpretation

1 FALLACIES INCIDENTAL TO X RAYS

Radiography is often used to estimate the degree of intestinal stasis by observing the time taken for a barium meal to pass through the alimentary tract. Repeated observations have taught me that this is a most fallacious and misleading method of estimating intestinal stasis. A more reliable method is to note the time that elapses before a dose of charcoal is passed completely per rectum. Comparison of the two methods shows that radiology very greatly exaggerates the degree of stasis which exists. In 150 consecutive cases investigated, charcoal was passed in an average of forty-two hours, whereas in the same patients the barium meal was not passed for an average of sixty-eight hours—an exaggeration of 60 per cent. Why there

should be this discrepancy is not obvious. Possibly part of the barium adheres to the mucosa, and gives a shadow after the bulk of the meal has passed. At any rate it is a fallacy to bear in mind, and apparently is one incidental to the method.

A fallacy which is a fruitful source of error is that due to the frequency of local spasm in the alimentary tract. Whether this spasm be the result of the barium meal or not is immaterial. At any rate, it is one of the fallacies incidental to radiography, and is often very misleading. It is said that this source of error may be eliminated by the administration of full doses of belladonna, but I am sceptical, for on many occasions, in spite of this precaution, I have seen spasm demonstrated, for instance in a typical hour-glass stomach, a diagnosis to which the radiographer adhered in spite of

FIG. 1.—Gastric spasm suggesting cancer

the absence of any clinical signs. A second radiograph, taken a week later after careful preparation, still showed an hour-glass constriction. At the operation no abnormality of the stomach was found, and the radiographic appearances were evidently the result of spasm secondary to a diseased appendix.

Fig. 1 is from a radiograph suggesting gastric carcinoma. The patient obviously had malignant disease, but although there were some symptoms pointing to the stomach as the affected organ, gastric analysis definitely excluded cancer of the stomach. Operation revealed a primary carcinoma of the liver.

It is obviously a fallacy to assume that an ulcer does not exist because one is not shown by the x rays. Duodenal ulcers are not often shown by radiography, but are frequently inferred to be present when they are non-existent. Whether gastric ulcers are shown depends mainly on their size and depth.

2 FALLACIES DUE TO TECHNIQUE

A gastric or duodenal ulcer may be missed if the exposure be not made in the dorsal, prone, and oblique positions. In one case, for example, a well marked gastric ulcer was not obvious on the plates taken in the dorsal and oblique positions. In another instance a marked depression due to an indurated ulcer on the anterior wall of the duodenum was visible only in the prone position. It is not often that a duodenal ulcer is shown so clearly, and the case is of interest as it was one in which operation would hardly have been justified apart from confirmation by the x rays. Thus

* Read in opening a discussion at a joint meeting of the Sections of Surgery and of Radiology and Physio-Therapeutics of the Annual Meeting of the British Medical Association Cardiff 1928.

patient's only symptom was a single severe hemorrhage, which was attributed to ptomaine poisoning. He had never had indigestion in the slightest degree, not even in the days preceding the attack. The only suspicious sign when I saw him a month after the hemorrhage, was marked rigidity of the right rectus muscle. As this still persisted a month later, duodenal ulcer was suspected. This is the only instance I have encountered of hemorrhage being the first and only symptom of a duodenal ulcer.

Errors in diagnosis may occur if the stomach be not adequately filled with the barium meal. Fig 2 shows a radiograph of the stomach which was diagnosed by the radiographer very confidently as inoperable carcinoma. There were no clinical symptoms of malignant disease and a radiograph by another radiologist showed a perfectly normal stomach.

3 FALLACIES OF MISDIRECTION

Not infrequently a radiological examination diverts the attention from the disease suspected to some abnormality of less serious import. Some years ago a lady was sent to see me with a history of recurrent attacks of appendicitis. Clinically, the doctor's diagnosis seemed to be correct. Routine examination showed albumin in the urine, so I had a radiograph of the kidneys, which revealed a right renal calculus. This led to a revision of the diagnosis. I removed the stone, believing this to be the cause of her recurrent pain. A few hours after she had left the nursing home she was seized with severe abdominal pain accompanied by a temperature of 104°F , and returned to the nursing home on the same evening with a very acute attack of appendicitis. In this case I think I should have disregarded the x rays as far as diagnosis was concerned, and removed the appendix first, leaving the stone to be dealt with later.

FIG 3—False suggestion of presence of appendix.

4 FALLACIES OF INTERPRETATION

The possibilities of errors of interpretation are numerous. This is not surprising when we remember that we are looking, not at a photograph, but at a shadow of something opaque to the x rays. In many instances the cause of the shadow must be a matter of inference, or even of guesswork. Gall-stones are a fruitful cause of this difficulty. Quite small gall-stones may be visible while large ones are not shown. Scybalaous masses may give a radiological picture indistinguishable from gall-stones as to situation and appearance.

Caténous glands and phleboliths sometimes mimic stones in the ureter very closely. Fortunately, a differential diagnosis can usually be made by passing a ureteric catheter. A pitfall to be avoided is that the stone may be passed between the taking of the radiograph and the operation. To guard against this contingency a second radiograph should be taken as short a time before the hour fixed for the operation as is convenient, and all urine

passed before the hour fixed for the operation should be carefully filtered through muslin. In spite of this precaution I have known a stone to be passed into the bladder between the taking of the radiograph at 11 a.m. and operation at 2 p.m.

Sometimes structures not existent are said to be there in a radiograph. Fig 3 is a radiograph showing an appendix, this was confirmed by another radiographer (Fig 4), but the appendix had been removed three years previously!

Gastric ulcers sometimes produce a radiological picture of cancer. At the operation a small gastric ulcer is found. Conversely, a gastric cancer may be present without any evidence on the film, although sometimes on screening it may be observed that the peristaltic waves become less active as they approach the pyloric end of the stomach. In one case a radiograph of the stomach, beyond a slight

spasm, showed no abnormality. Clinically the case was diagnosed as malignant. The whole of the cardiac end of the stomach was a mass of new growth almost obliterating the cavity of the cardiac half. In spite of the extent of the growth there was no suggestion of organic disease in the radiograph.

A mass of impacted faeces remaining *in situ*, even after free purgation, may give both clinical and radiographical evidence of obstruction. On one occasion a well marked filling defect was confirmed by a barium enema after apparently thorough clearing out of the bowels. Later the lump disappeared, and a further radiograph revealed a normal ascending colon. In such a case there is the

FIG 4—Another radiograph of Fig 3.

possible fallacy that the impaction of faeces may be due to early carcinoma not advanced enough to produce a filling defect, so that radiological confirmation may not be forthcoming until the disease is too far advanced for surgical treatment.

A not uncommon radiological diagnosis is adhesions at the right iliac fossa. In my experience this diagnosis is rarely confirmed on the operation table. The massive shadow seen in the radiograph may be, not distended ileum, but a dilated rectum or pelvic caecum. In one patient a diagnosis of intestinal obstruction in the small intestine

secondary to amoebic dysentery was made by the radiologist. At the operation there was a cicatricial contraction of the ascending colon, but no abnormality of the small intestines.

Adhesions are sometimes diagnosed because part of the intestine cannot be moved on the x-ray table. Such a diagnosis is often fallacious.

The last, and most insidious, fallacy to which I will refer is the claim that the progress of healing of a gastric ulcer can be gauged by radiography. This fallacy has arisen in connexion with the intensive alkaline treatment of gastric ulcer. We are asked to believe that by this method healing of a gastric ulcer can be brought about in three or four weeks. I think that most surgeons who have had much operative experience in these cases, and who have followed up their results, will agree that the pathological evidence is against such a claim. To believe that such pathological changes can occur in such a short time requires a liberal dose of credulity.

May I say in passing that naturally I do not question the correctness of the principle of reducing gastric acidity in gastric ulcer. More than twenty years ago I put

FIG 5.—Gastric spasm, appendix kink.

forward the view that gastro-jejunostomy is a physiological operation, and acts, not by drainage, but by diminishing the acidity of the gastric contents. This theory was ridiculed at the time, but is now accepted by most authorities. Whether the intensive alkaline treatment is a good method of achieving this is a subject outside the scope of this discussion, but I think the evidence on which its efficacy is tested is open to grave objections.

What are the facts? We know that the symptoms of gastric ulcer may be intermittent. Under treatment a patient may have long intervals of comparative freedom from pain, but the ulcer is not necessarily healed. Secondly, we know that after a successful gastro-jejunostomy the ulcer may not be healed for many months, and when healed there is usually some cicatrization at the site of the ulcer, which interferes with the normal peristaltic waves as seen on the screen. In spite of these facts we are told that with intensive treatment the ulcer may heal and the stomach be normal in three or four weeks. Is the radiological evidence sufficiently reliable to justify these assumptions? Experience teaches us first, that an existing ulcer may be missed altogether by radiography, secondly that an ulcer may be diagnosed radiographically which does not exist, thirdly, that the position of the patient at the examination may determine the apparent size of the ulcer and even whether it is shown at all. In view of the many possible sources of error it seems to me that radiological inferences as to the effect of the intensive alkaline treatment on a gastric ulcer, of the very existence of which

we are not certain, are to be accepted with great scepticism. In short, to talk of cure on radiological evidence is a fallacy.

To sum up, my remarks may appear to be destructive rather than constructive criticism, but I do not think this is really the case, for I would remind you that it is only by constantly bearing in mind the pitfalls which lie in wait for us that we can learn to avoid them. To most of you these pitfalls may be familiar, but even so, we cannot recall them to our minds too often. I am not speaking for the experts, but as one of the humble surgeons eager to pick up some of the crumbs of wisdom which may fall from the tables of the expert physicians and radiologists.

In conclusion I need hardly say that nothing I have said is intended to suggest that radiography is not of value. It is the infallibility of radiology, not its utility, which I wish to call in question. In its proper place its value is incontestable. Radiography combined with uroteric injections has enhanced enormously the accuracy of urological diagnosis. Without radiography the satisfactory treatment of fractures of the limbs would be impossible unless one resorted to operation in nearly every

FIG 6.—After appendectomy.

case. At present radiology is our greatest help in deciding as to the necessity for an operation in an individual case. But in abdominal diagnosis it is in its infancy, and must not be regarded as a final court of appeal. If it is so used it becomes a danger and a snare. The point I wish to emphasize once more is, that there is no such thing as a radiological diagnosis. In making a diagnosis all the aids which science can give should be called to our assistance, bearing in mind that they are helpers and not masters, and that radiology is only one of these aids.

We must not forget that every new invention, every new discovery, brings in its train disadvantages which cannot be wholly eliminated but may be minimized with care and attention. Radiology is no exception, so we must recognize its pitfalls and its limitations. In spite of these, its value is unquestionable and will be even greater in the future as we learn from experience how to make more accurate deductions from what we see.

Lastly, I would put forward two practical suggestions. First, if the radiographical findings do not support the clinical signs and symptoms they should be disregarded. An operation should rarely, if ever, be performed on a purely radiological diagnosis. Likewise an operation which is advisable for clinical reasons should not be deferred through lack of radiological confirmation. Secondly, I would urge closer co-operation between the surgeon and the radiologist. They should not work in watertight compartments. The surgeon should be present at the radiological examination and draw his own conclusions from what he

sees. Each should form an independent opinion and then in consultation try to agree on a diagnosis, likewise the radiologist and—may I suggest it?—the physician, should be present at the operation, to see how far the condition found is in accordance with their previous conceptions. Such a practice would be to their mutual advantage, and would lead to greater accuracy in diagnosis.

Above all, we must keep a sense of proportion. Too much science may mean too little common sense. Radiology, like any other invention, must be used with discretion and with that

Good sense, which only is the gift of Heaven,
And the no science fairly worth the given

THE FALLACY OF X RAYS IN ABDOMINAL DIAGNOSIS *

BY

F. HERNAMAN-JOHNSON, M.D. ABERD.,
D.M.R.C.B.,

Radiologist to the French Hospital London. Physician in Charge
of X-Ray Department Croydon General Hospital.

I FIND some difficulty in making a suitable reply to Mr Paterson's remarks, because, in the first place, I agree with many of his statements, and secondly, where I find myself differing, the defence seems so easy that I am inclined to distrust it, and to wonder if I have overlooked vital points. An unpleasant vision obtrudes itself of Mr Paterson—in the final broadside which, as opener, he will be privileged to deliver—pulverizing the whole position, and leaving the radiologists disconsolate among the smoking ruins.

However, this risk must be taken, and I will fire my first shot by challenging Mr Paterson's statement that the barium meal is of little value in the investigation of intestinal stasis. Mr Paterson prefers the administration of charcoal. I myself, following a *tu quoque* method, might inquire whether or not steps were taken to make sure that the whole of the charcoal passed in forty-two hours. One would be justified in asking this question, because in opaque meal work one may see a small part of the barium meal reach the rectum in a few hours, although the main mass lags far behind. The fallacy of the charcoal method lies, however, in the fact that no one can tell for how long it lay in any particular part of the alimentary canal. With the barium meal localized stasis can be observed. A good practical rule is to disregard stasis up to twenty-four hours, thus will eliminate most cases of so-called ileal stasis, and leave us with two important sites—the caecum and the rectum. I shall return later to the question of caecal stasis, stasis in the rectum, sometimes known as the dyschezia of Hurst, is a most important clinical entity, its existence may be suspected from symptoms, but can be proved only by x-ray examination.

As regards spasm shown by the barium meal, the significance of this appearance, and the means of differentiating it from local organic trouble, have occupied the best minds in radiology for three decades. It was originally taught by the late Dr. Carmen of the Mayo Clinic that persistent spasm of the stomach or duodenum which was not due to intrinsic disease could be abolished by belladonna. This doctrine now requires modification, but it remains a fact that spasm which resists all variation of posture, is present over long periods, and is not affected by belladonna given to the point of causing a dry throat and enlarged pupils, is nearly always an indication of organic disease somewhere in the alimentary tract or its offshoot, the gall-bladder. Mr Paterson's case was no exception, as there was a chronic appendix. It should also be remembered that, in some cases, the spasm, so far as the patient is concerned, constitutes the disease, if one can find a drug which controls the spasm, the symptoms are relieved. In short, the demonstration and differentiation of spastic contraction is a most important part of radiological diagnosis. Referring again for

one moment to Mr Paterson's case, the question arises whether a complete personal examination of the alimentary tract was made by the radiologist, as it would be unusual, though not impossible, for the appendix to escape notice under such circumstances.

Failure to find an organic lesion by x-rays is, of course, no proof that such does not exist. Such negative evidence should not, however, be despised. In a case where the suspicion is slight, it is a point in favour of a verdict of "not guilty", when the clinical evidence is weighty, negative x-ray findings at least exclude obstruction and gross deformity.

The importance of a proper technique is self-evident. The more frequent the examinations in a barium meal, and the greater the number of angles from which films are taken, the better are the chances of detecting an obscure lesion. Practical considerations, however, impose definite limits, and no doubt failures sometimes occur on this account.

As to fallacies due to misdirection, I think it is scarcely fair to include them at all. The demonstration of any possible cause of obscure symptoms should always be helpful. The trouble usually is that the radiologist has not a sufficiently free hand. A partial examination of the abdomen may result in misdirection, but a complete one should rarely do so. In Mr Paterson's calculus case, as in his case of gastric spasm, complete examination by an experienced radiologist would most likely have called attention to the appendix. A complete radiological examination includes barium meal, barium enema, cholecystography, genito-urinary tract, and the teeth, the latter are often omitted, or done by someone other than the radiologist making the principal examination. Hence sometimes an early recurrence of symptoms after operation. In hospital work especially it is often necessary to bring heart and lungs into the field of investigation. To use a single method of diagnosis in itself is a sufficient limitation, but when that single method is not fully employed, misdirection, as Mr Paterson calls it, is bound to occur.

Arriving now at fallacies of interpretation, we really come to grips with the matter at issue. There will always be errors in interpretation in x-ray work, as in other methods of diagnosis. I do not think, however, that the opener of the discussion has been fortunate in his instances, not one of which would be likely to mislead a competent radiologist who had seen the patients concerned, and knew their medical histories.

As to gall stones, a large calculus may fail to show because of lack of calerium content, and no one can exclude isolated stones by any known method. A bag of stones, however, if it does not show positively, will nearly always give negative shadows with cholecystography. As to scybalous masses, a combination of castor oil, enemata, and cholecystography will always clear up such a case beyond a doubt.

No radiologist of experience will attempt, on purely radiological grounds, to distinguish between an inflammatory mass, including penetrating ulcer, and malignant disease. If, however, an elderly patient shows gastric deformity, with or without ulcer niche, and gives a history of stomach trouble dating back only a few weeks or months, experience teaches him that in over 90 per cent of cases there is cancer. In writing his report he should, of course, carefully distinguish between x-ray findings and deductions which may in part be based upon history and symptoms. Those who consider that the radiologist has no concern with anamnesis and symptomatology should employ a lay radiographer to assist them, who would confine himself to technical matters.

A filling defect in the colon may, as Mr Paterson says, be due to impacted faeces. It should never be accepted as due to growth until castor oil and soap enemata have done their worst upon the unfortunate patient. And even if it vanishes under such treatment its discovery has nevertheless been valuable as a warning. Very early carcinomata seem to cause, at times, a sort of physiological block which results in faecal collections. If the block occurs a second time I should consider exploration imperative, and I am not at all sure that it ought not to be done without waiting for a second time. I laid

* Read in opening a discussion at a joint meeting of the Sections of Surgery and of Radiology and Physio-Therapeutics of the Annual Meeting of the British Medical Association Cardiff 1928.

stress on these points at a discussion held at the Royal Society of Medicine last year.

To fail to distinguish between a distended ileum, a pelvic caecum, and a dilated rectum is a radiological crime of the first magnitude. The clinical significance is in each case so different that the matter cannot be left in doubt. A caecum in its normal place can nearly always be seen separately from a distended ileum by manipulation in the oblique position where the caecum is pelvic. The matter presents difficulties. But a picture which is confusing at six or eight hours is often quite clear somewhat later. A pelvic caecum is fairly common, a distended ileum rare. In the few cases in which doubt remains after the meal examinations a full opaque cecum will usually clear the matter up. A simple manoeuvre serves to differentiate the rectum, a small injection, or even a glycerin suppository, will, if the mass is rectal, cause its partial or total disappearance.

As to the x-ray diagnosis of adhesions manipulation under the screen is very unreliable. Often a picture taken a few hours later will show that an apparently immovable portion of gut has in fact moved considerably. Suspected adhesions about the colon can, however, often be put to the test by an opaque cecum. A pelvic caecum is in itself of little importance, but one which does not rise on injection should always be regarded seriously, especially if it contains dense residue twenty-four hours after the main meal has passed on. Such a caecum usually has behind it an unhealthy appendix, which may give no localized signs or symptoms, and yet be responsible for gastric or duodenal disturbance. Hence the undesirability of x-ray examination confined to the upper part of the alimentary tract.

The demonstration of a genuine pelvic caecum, with a pool at twenty-four hours, and a probably infected appendix, can be accomplished only by x-rays. A chronic appendix in the ordinary position could no doubt always be detected clinically, but, in fact, is often overlooked. The reason is, I think, that pain in such cases is very sharply localized, and the radiologist palpating a visualized organ is unlikely to overlook what may easily be missed when the hand is unaided by sight. I have heard it said that heavy x-ray gloves will cause tenderness almost anywhere if used for palpation. Apart from the fact that strictly localized tenderness is alone of diagnostic value, the statement simply is not true. I have palpated with x-ray gloves thousands of patients in the past eighteen years, and I can certify that only a small percentage complained of pain in the right iliac fossa and in a still smaller percentage was tenderness localized in the appendix. It is, of course, a fallacy to declare an appendix necessarily free from infection because it cannot be incriminated by radiological methods.

Mr. Paterson's last criticism is of the value of x-ray evidence in demonstrating the healing of a gastric ulcer. The facts are simple. The ulcer makes a wide-mouthed pocket which fills with barium. With proper technique this pocket can be shown at will. If a time comes when the same process several times repeated fails to show the pocket its mouth must be closed. And when a year or two later the symptoms return, the demonstration is complete for the pocket is found again to be present. Here I am, for once, prepared to be dogmatic, and to say that seeing is believing.

In conclusion, I cannot allow to pass without adverse comment Mr. Paterson's dictum that if the x-ray findings do not support the clinical signs and symptoms they should be disregarded. This I consider to be a most dangerous statement not, perhaps, as Mr. Paterson means it but certainly as it will be interpreted by many who read his remarks. For example if the history and symptoms call attention to the digestive system and the radiological examination reveals changes in the lungs suggestive of tuberculosis, are these findings to be disregarded? This is no fanciful example but has happened several times in my own practice, the course of events subsequently proving that the dyspepsia was secondary to the lung trouble. To say that there is no such thing as a purely radiological diagnosis is to play with words. No physician practising radiology makes his report with

out taking into consideration the patient's history and symptoms. History and symptoms *plus* x-ray findings often leave no practical doubt as to the patient's complaint just as history and symptoms *plus* physical examination may in other cases be virtually conclusive.

So far my argument has been, in the language of another profession, that there is no case to go to the jury. But I am pleased to be able to close on a note of agreement with Mr. Paterson. I do believe in co-operation between surgeon and radiologist. In particular I think it essential that both should obtain the history of the case. A patient will often tell quite a different story to separate antechisms, and it is important that these histories should be correlated.

ERRORS IN THE INTERPRETATION OF RADIOGRAMS OF THE CHEST

THEIR CORRECTION BY TELE RADIOGRAPHY

BY

FF. ROBERTS, M.D., M.R.C.P.,

ASSISTANT PHYSICIAN (IN CHARGE OF THE X-RAY DEPARTMENT)
ADDENBROOKE'S HOSPITAL, CAMBRIDGE

(With Special Plate)

In the ordinary method of radiography of large and deep parts of the body such as the chest, when the x-ray tube is situated at 2 ft. or less from the film, considerable errors are introduced owing to the divergence of the rays. Though these errors are known to exist, their magnitude and importance are, in this country at any rate, not sufficiently recognized. It is the purpose of this article to show how misleading such errors may be, and how by the simple method of tele radiography they can be reduced to a minimum.

The errors are of two kinds: (1) errors of position, (2) errors of size, in addition there is (3) faulty definition.

1. ERRORS OF POSITION

Fig. 1 illustrates the projection upon the film of the ordinary postero-anterior view of the chest, the central

FIG. 1.—Postero-anterior projection through the upper part of the lung showing displacement. See text.

ray passing through the mid-line of the body at the level of the third costo-sternal articulation. A and B are two points lying in the same horizontal plane on the anterior and posterior surfaces of the lung respectively. As projected upon the film (A'B') A appears to be higher than B. Moreover a point, C, lying at a lower level than A and B, is projected above A but below B. Fig. 1 (plate) shows the postero-anterior view of the chest, the distance between the tube and the film being about 2 ft. On the chest four coins of equal size have been placed. Coin A lies on the anterior wall just below the inner end of the clavicle. B lies on the posterior wall opposite the fifth rib in exactly the same horizontal plane as A. The central ray is at the level of the third costo-sternal articulation. It will be seen that B appears to be supraclavicular, whereas its true position is well below the apex of the lower lobe. The two coins C and D are placed on the anterior and posterior walls of the chest respectively in the same horizontal plane (level of the third costo-sternal articulation), through which the central ray passes. They are both 34 in.

from the mid-line. It will be seen that D is projected well to the outer side of C.

This displacement is very little realized, and is of the greatest importance in the correlation of the radiological with the clinical findings. In a radiogram taken in this way the part of the lung field which is projected above the clavicle is not the true supraclavicular part, in other words, it is not the view which the observer would get were the patient standing in front of him with a transparent chest wall. In viewing the supraclavicular part the observer is looking into a section of lung shaped like a truncated cone, the narrower posterior end of which points downwards and towards the middle line so as to include the upper part of the lower lobe. The plane of the lung, which is just below the clavicle, is projected partly above and partly below the clavicle. The upper part of the lung is, in fact, distorted in much the same way as the roof of a house in an architect's elevation. Similarly when he is viewing the costo-phrenic angle he is looking not directly backwards, but upwards and towards the middle line, and when he is viewing the lateral wall of the chest he is looking slightly inwards. The radiogram as a whole is in reality the integration of an infinite number of parts, each of which is the projection of a cone of lung tissue. The farther any part is from the film and from the mid-line the greater is the distortion which it suffers. Even when he realizes this fact the observer finds it very difficult to transform the visual into an adequate mental image.

This important point can perhaps be expressed more simply in the following way. Let us suppose once more that the chest wall is transparent. In order to obtain a naked-eye view corresponding to the radiogram the observer would have to stand not in front of but behind the patient, with his eye in the position occupied by the x-ray target—that is to say, at the level of the third costo-sternal articulation and about one foot away from the posterior surface of the body. This fact was first pointed out by Cotton.¹

The worst feature of this error is that different parts of the lung are displaced unequally, the greater the distance from the central ray, the greater is the displacement. The consequence is that a small change in the position of the central ray alters the projection considerably, magnifying the error on the side from which the central ray has moved, and diminishing it on the other. If the central ray passes through the fourth instead of the third costo-sternal articulation the error will become greater in the apical region but less at the base. No two radiograms of the same chest, therefore, present the same appearance unless the central ray has the same position in both cases.

FIG. 2.—Projection through horizontal section through the chest showing magnification.

(Fig. 2) be situated 8 in from the film, the tube-film distance being 2 ft. The projected diameter is XY'. Let O be the position of the tube. It is obvious that—

$$\frac{XY'}{XY} = \frac{OX'}{OX} = \frac{24}{16}$$

$$XY' = \frac{3}{2} XY$$

and the area of the projected cavity is nine-fourths or two and a quarter times the true area.

In other words, from the clinical point of view the radiological appearance always exaggerates the case. Provided the error were always of the same magnitude it would not matter so much, since those who have to interpret the radiogram would know it and learn to make mental allowance for it. This, however, cannot be done, since the error varies with the distance from the film of the structure concerned.

3 FAULTY DEFINITION

The blurring of the edges of the two coins on the posterior wall of the chest in Fig. 1 is very obvious. It is, of course, due to the penumbra formed by the blunt focus of the tube. No tube can be made with a point sufficiently fine to avoid it. But even if a point focus could be obtained, faulty definition would still occur, and for this reason. In the normal and abnormal structures found in the lung we are dealing with fine differences in the depth of shadows. Let the triangle A (Fig. 3) represent the varying depth (not size) of such a shadow tapering to a point. Let the shadow be projected in the form A'.

FIG. 3.—For explanation see text.

The inevitable result will be that the grading of the shadow will be, so to speak, more prolonged. In other words, relative opacity will be exaggerated and blurring will result. The image exhibits a greater gradation of shadow than the object warrants.

ORTHODIAGNAPHY AND TELE RADIOGRAPHY

In order to avoid the errors above described two methods are employed. These are orthodiagraphy and tele-radiography. In the former the patient stands behind a fluorescent screen the position of which is fixed. The tube can be moved laterally and vertically in such a way that the central ray can be projected through any part of the chest in a plane at right angles to the screen. Using a very small diaphragm, the operator with one hand moves the tube, while with the other he sketches point by point the outline of the organ examined. Since each point is the projection of the central ray, the outline thus obtained represents the true size of the organ. The sketch is then transferred to tracing paper. Alternatively a pencil moving automatically with the tube is used. This method, which was devised by Moritz and developed by Groedel, is now extensively employed on the Continent, particularly in Germany and Austria. It has the advantages of rapidity and cheapness, since films are not required. It has two great disadvantages: first, while it provides an admirable method of recording bold outlines such as the borders of the heart, it is impossible by this means to follow fine details; secondly, the record thus obtained is subjective and not objective.

Tele-radiography simply consists in increasing the distance between the film and the tube so that the errors due to divergence are reduced to a minimum consistent with practice. The distance usually employed is 2 metres, or about 6 ft. The rays issuing from a tube at this distance may for practical purposes be considered to be parallel. This method, which was first suggested by Kohler, is coming into increasing favour, but in my opinion has in this country not yet received the attention which it merits. One reason for this is the incidental result of the improvements which have been made in the construction of x-ray apparatus. Such improvements have, rightly enough, had for their main object the protection of the operator. Most screening stands are so constructed that the patient must stand close up to the tube. But while this arrangement is admirable both from the point of view of protection and for the purpose of a visual examination, it is not suitable for obtaining a true picture. The old objection that a long exposure is necessary is in these days of powerful plant no longer valid.

My own procedure is as follows. Using a screening stand in which the tube and screen move together, a screen examination is first made. The patient comes out of the screening stand and sits on a stool fitted with a film

FIG I—Postero-anterior view of chest taken at 2 ft. A, B, C and D are four similar coins. A and C being on the front wall, B and D on the back wall. B is situated directly behind A and D directly behind C. Note magnification and displacement of B and D. B though opposite the upper part of the lower lobe appears to be above the clavicle.

FIG II—The same but at 6 ft instead of 2 ft. Note the correction in size and position of B and D.

FIG III—Cavity in the left lung taken at 2 ft. The cavity is indicated by cross lines.

FIG IV—The same but at 6 ft.

FIG V—Cavity in its true projected size (unreduced) from FIG III.

FIG VI—The same (unreduced) from FIG IV.

AN UNUSUAL CASE OF URETERAL STONE

THE BRITISH MEDICAL JOURNAL 601

holder (Fig 4) This is a very simple piece of apparatus which was put together in a few minutes. It consists of an ordinary office stool 2 ft 6 in in height, above one side of which projects a vertical board 2 ft in height and 1 ft in breadth, supported on a pillar which is screwed to the stool. The lower edge of the board is 8 in above the seat. The patient sits facing the board with his legs protruding beneath it, one leg on each side of the pillar. The film in its cassette having been placed upon the board, the patient presses his chest against it with his arms folded behind the board. This position not only immobilizes him, but also has the incidental advantage that it causes the maximum abduction of the scapulae, with, in consequence, the least possible obstruction of the lung fields by these bones.

FIG 4.—Stool and film stand used for tele-radiography

The stool is placed so that the film is 6 ft from the tube. The positions of the tube and stool have been previously adjusted so that the central ray passes through the mid line of the body at the level of the third costo-sternal articulation. These positions are standardized once and for all, allowance being made for varying heights of patients. Suitable marks are made on the upright and arm of the tube-stand, while the position of the stool is marked on the floor. Tube and stool can therefore be adjusted rapidly in the recumbent position.

For patients who have to be examined in the recumbent position, the best method is to put the patient on a stretcher on the floor and to use a vertical stand with the tube as high as the pillar will allow. It is not necessary to turn the patient over on his face, for the following reason. The ordinary close up antero-posterior view of the chest (the rays passing from front to back) is unsatisfactory, since the heart and great vessels lying nearer the front than the back wall of the chest cast an exaggerated shadow. With the tube at 6 ft, however, this exaggeration is reduced to a minimum. In fact, there is very little difference at 6 ft distance between the antero-posterior and the postero-anterior view. It will therefore be seen that the method is very simple, the only trouble being involved in the initial standardization of the position of stool and tube.

Fig II is the same chest as Fig I, but taken in this way. It will be observed that coin B is almost directly behind A and approximates closely to it in size. This, ever, is slightly to the outside of C, owing to the fact that the patient is turned slightly to his left. This can readily be determined by comparing the positions of the two sterno-clavicular articulations in relation to the edges of the vertebral column. It will be seen that the inner end of the left clavicle is slightly farther out than that of the right. Had the patient been sitting quite square D would have been almost directly behind C. Again, taking the case of a structure situated 8 in from the film let XY be the actual diameter of the structure and X'Y' the diameter of its shadow. We have

$$\frac{X'Y'}{XY} = \frac{OY'}{OX} = \frac{6 \text{ ft}}{5 \text{ ft } 4 \text{ in}} = \frac{9}{8}$$

$$\text{while } \frac{\text{area of } Y'}{\text{area of } Y} = \frac{81}{64}$$

The exaggeration in area is therefore about nine sevenths, as compared with nine-fourths in the close up view. It will further be observed that the outlines of coins B and D, instead of being blurred as in Fig I, are now as well defined as those of A and C.

Space prevents my showing many instances of the various conditions in which the superiority of the tele-radiogram is manifest. I shall confine myself to one case, illustrated in Figs III and IV. These show in the left lung an egg-shaped ring shadow, probably due to a cavity. The position and extent of the cavity are indicated by cross lines. Fig III was taken at a distance of 2 ft and Fig IV at

6 ft. It will readily be understood that in the process of reduction the difference has become considerably diminished. I have therefore reproduced in Figs V and VI the cavity in its true projected size, Fig V is at 2 ft, Fig VI at 6 ft.

Enough has been said to show how misleading the ordinary radiogram of the chest may be. Owing to the error in size the film always shows the case to be more serious than it really is, while the error in position must often lead to considerable discrepancy between the radiological evidence and the evidence deduced from physical signs. It is also clear that, as records of the progress of a case—for example, the changing size of a tumour, cavity, or aneurysm—successive radiograms lose much of their value unless they are taken under the same standard conditions. It seems to me to be highly desirable that for comparative purposes a conventional standard should be adopted, the two constants being the distance of the tube from the film and the level of the central ray. Thus, of course, is not to say that other views are unnecessary. I should be the last to minimize the importance of special views, such as the Kreuzholz view suggested by Fleischner for revealing interlobar effusions, but I feel sure that the adoption of a standard tele-radiogram would be a step forward in the radiology of the chest.

I have to thank Mr Mann radiographer at Addenbrooke's Hospital, for his skilful technical assistance.

AN UNUSUAL CASE OF URETERAL STONE

BY
HFRBFRT WILLIAMS, M B, F R C S,
SENIOR HONORARY SURGEON, ROYAL SOUTHERN HOSPITAL LIVERPOOL
AND
C THURSTAN-HOLLAND, D L, M CH, F R C S,
LECTURER ON RADIOLOGY, LIVERPOOL UNIVERSITY

(With Special Plate)

The investigation of this case presents many features of interest both from the urological and radiographic points of view. The short history of the case is as follows.

Miss M, aged 46, in May, 1927, had a sudden pain in the left loin lasting from four to five hours, accompanied by frequency of micturition. The temperature was normal.

In October, 1927, she had very severe pain in the left loin, she was writhing in agony and could not keep still. This was associated with a rigor, sweating, and violent retching. There was no great frequency of micturition but the urine was acid and contained a slight amount of albumin, pus cells, staphylococci, and coliform bacilli. In ten days she was well again.

In November, 1927, she had a similar attack to the last but it was more severe and lasted a fortnight.

Between the attacks she had persistent frequency of micturition and sharp pain in the urethra after the act, persisting for varying times afterwards.

In December, 1927, an x-ray examination was made elsewhere. Various shadows were found in the pelvic region, where it was suggested that there might be a stone in and it was also suggested that there might be a stone in the pelvis of the left kidney.

On February 2nd, 1928, C T H examined her and took the usual films to cover the whole stone area. These radiographs showed that there was no stone in either kidney, and both kidneys appeared to be normal in size and position. In the pelvic area were shown the same shadows which had previously been found, and all of them were in exactly the same position. (See radiograph, Fig 1.) This showed that no stone had passed in the interval from the left kidney. It was obvious that the only shadow to be considered was the rounded one on the left side of the pelvis. This was not in the usual line of the ureter, it was round in shape, and it was in exactly the same position in two radiographs taken at intervals of a few weeks. C T H very definitely decided against it being a shadow of a ureteral stone.

Now came the first piece of luck. C T H was out when the surgeon in charge of the case (H W) came in to see the

the films C T H's partner (J H M) showed him the films and also agreed that it might be a stone in the ureter. The result of this was that it was decided to have an opaque catheter passed, arrangements were accordingly made, and the patient was told all about it. The point is that in all probability if C T H's opinion had been given in the first place then no further x-ray proceedings would have followed.

Having explained everything to the patient, it was settled that the opaque catheter should be used not withstanding, and, under general anaesthesia, the cystoscope was passed (she refused to undergo cystoscopy with a local anaesthetic). The left ureteric orifice was inflamed and an area of cystitis extended from it on to the trigone. The ureteral catheter (sold as an opaque one) passed easily right up the ureter without a hitch of any kind.

Stereoscopic radiographs were taken and the films immediately developed. Our consternation was great when no shadow of the catheter was present (See Fig 2.) (It is to be noted that the patient knew exactly what to expect and would have to see the radiographs.)

The next step was not very obvious, as no other catheter was available and the patient was coming round from the anaesthetic, then, very fortunately, it occurred to one of us that as the catheter was not opaque there should be a lumen into which opaque fluid could be injected. Umbrenal was injected and a radiograph (Fig 3) obtained, the catheter was partially withdrawn and the radiograph shown in Fig 4 taken. The catheter was then entirely withdrawn, and these two films were developed. It is obvious that a satisfactory explanation of these films was not easy. Some of the opaque fluid had apparently passed down beside the catheter, which was not touching the doubtful stone shadow, and just about one inch above the shadow had passed away from the catheter as if to enter a sac, and had surrounded the shadow, which in the second of these films (Fig 4) appeared as a negative shadow—that is, as a less dense area in the middle of the umbrenal shadow.

It then occurred to us to take one more plate, and this was taken about twenty minutes after the withdrawal of the catheter, when urine and umbrenal filled the lower ureter (See Fig 5).

The exact diagnosis then became clear. The ureter was enormously dilated from the spot where it entered the bladder wall, and the shadow was, in fact, caused by a stone in the dilated ureter. Originally there appears to be no doubt but that the stone was impacted at the site of the entrance of the ureter into the bladder, and then, having caused the dilatation of the ureter, had moved upwards. It was really a stroke of luck that the catheter was non-opaque to x rays, as if it had been opaque nothing further would have been done and it would not have helped to an accurate diagnosis. Then, again, it was most fortunate that it was hollow, and that some opaque fluid was at hand. Even then, without the somewhat lucky last radiograph, there would still have been some doubt as to the exact position of affairs. One other thing we should, of course, have done was to have taken a radiograph of the kidney after the injection. In the heat of the fray this was forgotten.

On February 9th, 1928, the non-protein nitrogen in the blood = 37 mg per cent. The next day, under ether anaesthesia, cystoscopy was again done, for the double purpose of carrying out the dye excretion test and attempting to bring the stone down into the bladder. Dye appeared from the right ureter in five minutes, but none appeared from the left in fifty minutes. An "Eynard" ureteral dilator was used in the attempt to bring down the stone. This was unsuccessful, and all that came away was some septic-looking granulation tissue.

This procedure induced another attack of pyelonephritis, and examination of the urine revealed the presence of blood, pus, squamous epithelium, mobile bacilli, and staphylococci. The attack lasted five days.

The question of operation for removal of the stone had now to be considered. The easiest method of approach would have been through a suprapubic incision with displacement of the peritoneum. This route was decided against because the patient was particularly anxious not

to have more than one operation. The effluent from the left kidney was grossly infected, the ureter was markedly dilated, and the patient had had three attacks of pyelonephritis. In the case, therefore, of the stone being removed by direct exposure of the pelvic ureter it was impossible to promise that the kidney would recover and not require subsequent removal. It was accordingly decided to expose the kidney by the usual lumbar incision, then if the condition of the kidney called for removal, this could be carried out, if, on the other hand, it was considered recoverable, it could be left, and the stone removed through an incision in the ureter.

At operation the kidney was found to be slightly enlarged, and the pelvis and calyces a little dilated. The ureter was dilated to a moderate degree, and on incising it some turbid urine containing flakes of pus escaped. The mucous membrane of the ureter was glistening and did not show any gross inflammatory changes. It was therefore decided not to remove the kidney.

A short incision was made into the ureter. A special bent long spoon (Fig 6) was passed down to its lower end and a small oxalic acid stone was brought up the first time. The incision in the ureter was closed and the lumbar wound sutured and drained.

The patient made a normal recovery and left the nursing home on April 12th.

On June 21st she reported that she had had no further attack of pain in the loin, there was no frequency of micturition or pain at the end of the act. Her general state of health was very good and she could walk three miles.

No cystoscopic examination has been carried out since the operation, nor is she likely to consent to one being done.

The case is extraordinarily instructive from the radiographic point of view, and demonstrates clearly the difficulties which may sometimes arise, and the ease with which an exact diagnosis might have escaped us.

It is a very easy matter nowadays to show stone shadows and the shadows of other things. Differential diagnosis of these shadows may be, and often is, a matter of great difficulty, and even a large experience may fail one.

From the urological point of view it shows the difficulty of giving an opinion as to the exact condition of the kidney by means of the ordinary urological investigation. Such investigation in this case suggested the presence of an extensively disorganized kidney, or at any rate one of very little functional value. Exploration at operation, however, indicated a recoverable kidney and one well worth saving, a decision that has been thoroughly justified by the subsequent history of the patient.

FIG 6

AFTER-EFFECTS OF SURGICAL PROCEDURES IN CASES OF PULMONARY TUBERCULOSIS

I—THE SURGEON'S POINT OF VIEW *

BY

A. TUDOR EDWARDS, M.D., M.Ch. Cantab., F.R.C.S.,
Senior Surgeon in charge of Out-patients and Joint Lecturer in
Surgery, Westminster Hospital. Surgeon to the Brompton
Hospital for Diseases of the Chest.

THE surgical treatment of pulmonary tuberculosis has become of increasing importance during the last few years, and although a large amount has been written about it, I do not propose to take up your time with a recapitulation of published results, but shall confine myself entirely to my own personal experiences.

The final test of any method or methods of treatment can only be judged by their end-results, but the satisfactory results of pneumothorax treatment, in properly selected

* A paper read in opening a discussion in the Section of Tuberculosis of the Annual Meeting of the British Medical Association Cardiff 1928.

cases and when adequately carried out, have encouraged the surgical methods when the minor methods are impossible.

After-results will depend upon a series of factors, and I propose to discuss these under different headings before giving the actual figures of cases upon which operations have been performed.

FACTORS INFLUENCING THE AFTER-RESULTS

(a) Right Choice of Cases

In considering this factor it must be realized at the outset that, as a general rule, acute early phthisis is excluded so far as all major surgical procedure is concerned. The cases which are almost invariably submitted are those of the chronic third stage type, and in considering results comparison must be made between cases of this kind which have been submitted to operation and those which have not. Up to the present time, so far as this country is concerned, it is only in cases in this stage, which, in spite of the usual measures, are showing a tendency to become worse, that surgical treatment is contemplated by the physicians in charge. It is quite unnecessary here to bring forward figures of the results of sanatorium and other forms of medical treatment in late disease except to say that there is great scope for improvement, and it is my contention that in a certain proportion of these cases surgery can give much help.

The chief factor influencing one's choice is the condition of the "better" lung. It is extremely rare that there is no evidence, either clinical or radiological, of the previous existence of contralateral disease. This alone is not necessarily of significance, but one adopts as a working hypothesis the rule that this disease shall have shown no activity for at least three months before operation.

In cases of doubt it has been my custom, following the practice of Sanerbruch, to make use of the minor operation of phrenic evulsion, which, by putting an increased strain on a doubtful "better" lung, may enable us to determine any liability of the disease to spread therein. I have had no case so far, in which the major operation was contemplated, where increased activity of disease in the better lung has resulted from phrenic evulsion, but this does not necessarily diminish the value of the minor operation for the purpose just indicated.

In certain instances I have been persuaded to undertake thoracoplasty in the presence of active disease of the opposite apex, but these cases have been chosen with particular care and have been under control by a competent physician. Active disease in the better lung in situations other than the apex is a definite contraindication to thoracoplasty, although in one case with activity in the middle zone in which thoracoplasty had been successfully performed the disease settled down and is now inactive after two years.

Cases in which artificial pneumothorax has been induced and carried on for some time—months or even years—and in which, following cessation of refills, the disease becomes active again, almost invariably respond well to major surgical collapse. It is only rarely possible to reproduce the artificial pneumothorax, and time should not be wasted in other measures before submitting these cases to thoracoplasty.

Another type in which thoracoplasty is of great value is that in which, either during artificial pneumothorax therapy or as a result of spontaneous pneumothorax, fluid develops, which later becomes purulent. The fluid will require aspiration at intervals, with or without gas replacement, and there is a constant danger of secondary infection, either from within, by way of a small pulmonary fistula, or from without after repeated aspiration. Secondary infection with pyogenic organisms is always a serious and often a fatal complication, and one which should be avoided at all costs.

(Where this complication has occurred I would urge that when aspiration or drainage is necessary it should be done, if possible, through the front of the chest, so as to allow a clean field for collapse operations over the back, when recovery is sufficient. The cavity can always be kept empty by means of suction, and the area at which an empyema naturally points is always in this region.)

Cases in which drainage of an infected tuberculous empyema has been performed should, other circumstances

permitting, be submitted to thoracoplasty as soon as is reasonably possible, since delay may result in the establishment of lardaceous disease. The ultimate prognosis in these circumstances is always very poor, and provides a strong argument for adapting radical measures for tuberculous empyemata before secondary infection has supervened.

Of the series of cases analysed later, nine had thoracoplasty for tuberculous empyema. Five of these (four being sequelae of spontaneous pneumothorax and one a tuberculous effusion occurring during artificial pneumothorax treatment) had thoracoplasty performed with excellent results, the pleural layers becoming approximated and adherent. All these patients are now on full work. The other four had sinuses present as a result of previous drainage operations for secondary infection. Of these, one is quite well except for a minute sinus, another died owing to extension of disease to the other lung within a few days of the operation, the third succumbed to lardaceous disease three months after thoracoplasty, although the operation wound healed by first intention, the fourth, although alive, is gravely ill.

Apart from the types mentioned previously it may be taken in general that thoracoplasty is indicated in all those cases in which complete unilateral artificial pneumothorax is indicated, with the proviso that more care should be devoted to establishing the presence or absence of active disease in the better lung, and that early cases should be given an extended trial of all other medical measures before operation is considered.

There is, however, a tendency to wait too long, in many cases until the patient has been weakened by repeated haemorrhages or until practically all lung parenchyma has been replaced by fibrous tissue interspersed with multiple cavities. It is not to be expected that any operation can offer hope of relief in the terminal stages of cases of this sort, and, apart from this, surgical operations, which may be excellent in appropriate circumstances, will incur a not unreasonable odium if performed at this stage. Surgical procedures offer considerable help in cases of haemoptysis which cannot be controlled by ordinary measures and in which artificial pneumothorax cannot be induced.

(b) The Type and Extent of the Operation

Increasing experience has steadily convinced me that the ideal to be sought is an adequate collapse of the whole of the involved lung. This can best be obtained by performing a preliminary phrenic evulsion and subsequently a two-stage thoracoplasty from the first to the tenth ribs posteriorly. In the majority of cases these operations are done with a short interval, seven to fourteen days elapsing between the phrenic evulsion and the first stage, while the interval between the two stages of the thoracoplasty is from sixteen to twenty-one days.

In my experience phrenic evulsion definitely diminishes the reaction of the first stage of thoracoplasty, apart from its subsequent compression value. Moreover, the division of the operation for thoracoplasty into two stages has undoubtedly lowered its operative mortality, and unquestionably allows of its successful performance upon individuals in whom it would be otherwise impossible.

With regard to partial thoracoplasty, it would seem, even with resection of considerable portions of a few ribs, that the compression is inadequate, since effective collapse of the thoracic cage is prevented by the remaining rigid chest wall.

There are two measures suitable for the production of localized collapse—namely, phrenic evulsion and pneumolysis.

The former operation is of a minor type and should, if carefully and properly performed, be without mortality. For various conditions, including tuberculosis, I have performed it 120 times, without surgical complication of any sort. In tuberculosis, however, it is only in a small proportion of cases that the result of this operation alone is adequate. In certain instances it has benefited the patient sufficiently to admit of the performance of thoracoplasty several months later, and in the rarer cases of basal tuberculosis it may be all that is required. As an accessory operation there are several indications for its employment. In pneumothorax cases where basal adhesions are present

and in which refills are followed by an irritating cough, or in which adhesions are preventing the collapse of cavities in other situations, very considerable relief can be obtained by phrenic evulsion.

The question whether phrenic evulsion should be used in a greater number of cases of artificial pneumothorax, without special indication at the time, and with a view to prevent full expansion of the lung after cessation of the pneumothorax, is debatable.

Pneumolysis, or the separation of the lung and the two layers of the pleura from the inner chest wall, does allow of very definite localized collapse if the space is filled by some extraneous substance which is retained. Fat is probably the best substance, and may be obtained either from the patient's abdominal wall or from a lipoma from a patient of a corresponding blood group. The chief disadvantage of the operation is its localized nature in a disease which is much more generalized. It has a very definite value, in my experience, where a residual cavity remains at the apex after thoracoplasty.

(c) Anaesthesia

There has been much discussion as to the best method of anaesthesia for these operations. It is widely recognized that ether has an irritating effect upon the lungs, and it is but rarely used. Some surgeons operate under chloroform anaesthesia, but this offers the disadvantage of the depressing effect of the drug on the heart, and is a factor which, in these cases, where the blood pressure may be as low as 90, cannot be ignored.

Local anaesthesia, most commonly used on the Continent, largely because of the lack of skilled anaesthetists, can be satisfactorily employed as regards elimination of pain, but the sensation of pulling and pressure which patients experience in such a large operation has a very definite mental effect. They may not suffer from surgical shock, but they do suffer from a mental shock.

The earlier cases of this series were performed under local anaesthesia, but for the above reasons I now employ a combination of gas and oxygen inhalation with local anaesthesia, and with this I am well satisfied.

(d) Operative Mortality and Complications

The operative mortality depends upon several factors, most of which have been previously enumerated. Pulmonary embolism, unfortunately, cannot by any known means be entirely eliminated from the complications of any surgical procedure, this accounted for one of the operative deaths.

Shock as a cause of death should be largely, if not entirely, eradicated by careful pre-operative treatment, suitable anaesthesia, and rapid operating—by operation in two or more stages where required—and finally, by careful choice of the cases. These factors will all depend upon the skill and experience of the operator and his assistants.

Rapid spread of disease in the opposite lung will occasionally occur, and when this results in death under three weeks it must be considered as due rather to activation by the operation than to the compression. Two patients developed such a rapid spread in the opposite side (within three weeks from operation), from which death resulted.

Wound infection, should it occur, is likely seriously to complicate convalescence, and death has been reported as a result. It is possible that infection may very occasionally spread through the pleura from the lung, but a more likely cause is the introduction of sepsis from without, either at or subsequent to operation. The only cases in which the technique cannot be completely blamed are those with secondarily infected discharging sinuses of the chest wall, but even then careful sequestration of the infected area should eliminate the possibility of infection in the operation wound.

The above remarks apply more especially to thoracoplasty. No complications and mortality in phrenic operations have occurred, and in five cases of apicolysis, with fat transplants, there was no operative mortality, and only one case in which any complication occurred, this is described later.

(c) After-Treatment

It is not necessary here to enumerate the smaller items of the immediate post-operative treatment, attention being drawn only to wider principles.

In phrenic evulsion and apicolysis there is little after-treatment. In thoracoplasty the essential point is to take advantage of the soft nature of the parietes before rib regeneration occurs.

It has been my practice for some time to apply to the chest wall small bags containing lead shot and varying in weight so as to obtain the requisite compression. I usually start this treatment about seven days after each stage of the operation, and begin with a weight of 6 or 7 lb. This is applied to the subclavicular region as long as the patient can comfortably support it, the position of the bag is then changed to the axilla, with the patient lying on the sound side, for a similar period. This pressure is applied twice a day. In those with rigid chest walls, and especially in patients with tuberculous empyema, considerable weights are required, as much occasionally as 24 lb. Subsequently, a special form of belt is worn for several months.

The enforcement, at a later stage, of a period of sanatorium regime, varying from three to six months, I regard as one of the points most essential to success.

Thoracoscopy and Cauterization of Adhesions

The following figures show the limited value of this procedure, and also demonstrate the fact that out of eleven cases in which cauterization was successfully performed in only just over half of these was the end-result very good.

Thoracoscopy performed in	26 cases
Cauterization was successful in	11 cases
The end result of artificial pneumothorax treatment and cauterization was good in	6 cases

Apicolysis

The number of cases in which apicolysis was performed for tuberculosis was 5. In 3 of these it was supplementary to thoracoplasty for incompletely collapsed apical cavities, and in all these it was successful in so far that the fat graft used healed *in situ* by first intention and that the sputum present was very much diminished. In another it was performed as a supplementary operation to an incomplete pneumothorax. Healing again resulted by first intention, but the result was unsatisfactory, chiefly, I think, owing to bilateral active disease.

In the last case apicolysis was performed for haemoptysis from an apical cavity, which had reopened after long continued satisfactory artificial pneumothorax treatment. In this case the fat graft became surrounded by a layer of effused serum, and the process of stripping the lung and both layers of pleura from the chest wall, initiated by the operation, was continued after operation by the retraction of the fibrosed lung. This resulted eventually in a large extrapleural cavity, which necessitated closure by thoracoplasty.

Phrenic Evulsion

The cases of tuberculosis in which this operation was performed numbered 79. There were no operative deaths or complications. The cases may be subdivided into

(1) Cases in which phrenic evulsion has been performed as a preliminary to thoracoplasty and of which the results are included under that heading, these numbered 40.

In a few of these cases the preliminary operation had been done several months before the thoracoplasty, and the improvement resulting therefrom justified the thoracoplasty, which was primarily out of the question, owing to both the general and local conditions.

(2) Cases in which phrenic evulsion has been the sole surgical procedure—these numbered 39 and may be classified as follows:

(a) Cases with haemoptysis with complete cessation of bleeding	4
(b) Supplementary to artificial pneumothorax	7
Much improved	6
Temporarily improved died some weeks later of bilateral disease	1

The heading "much improved" refers to disappearance of symptoms due to diaphragmatic adhesions, such as persistence of sputum, and of temperature, and to

intractable cough, most marked after refills. A point of some significance is that it has been possible considerably to increase the time intervals between refills in all cases after phrenic evulsion, a point of economic significance where patients have to travel some distance for their refills.

(c) Cases of tuberculosis without complications and in which artificial pneumothorax was not possible	28
Much improved	13
Improved	8
No change	5
Temporarily improved died subsequently	2

"Much improved" refers to cases in which temperature, pulse, and sputum were reduced to normal limits and the general condition was good. "Improved" refers to cases in which there has been a definite diminution in the quantity of sputum, a lower level of pyrexia, where present, and improvement in the general condition. In some cases the presence of bilateral active disease has prevented the full effect of the operation. Those cases in which "no change" has occurred have also been bilateral, and some of them were patients with very advanced disease. The two cases of subsequent death had both been cases of acute bilateral disease, in which the operation had been performed on the side of the more extensive lesion.

Thoracoplasty

Thoracoplasty had been performed for tuberculosis in 59 cases up to May, 1928, with the following results

Alive and well	22=37.3 per cent
Alive much improved	10=17.0
Alive slightly improved	2=3.4
Alive no change	2=3.4
Alive sanatorium treatment not completed but doing well	10=17.0
Died within three weeks of operation	4=6.8
Died later	9=15.1

Those alive and well consist of patients able to carry on their occupations, varying from heavy manual work to clerical work, in the great majority returning to their pre-invaliding occupations, if any. Those alive, much improved, consist of patients who are able to do light work. The slightly improved cases are able to get about but are unfit for any work.

The operative deaths occurred as follows: the first on the third day, from a pulmonary embolus, the second, six days after the first stage operation for septic tuberculous empyema, from acute spread in the opposite lung, the third, twenty days after the first stage operation, of acute broncho-pneumonic spread in the opposite lung, the fourth, from sudden heart failure, eight days after the second stage operation.

The patients dead subsequent to operation survived for periods ranging from three months to four years and two months. One patient, who was apparently well as regards his pulmonary condition, died suddenly in the street from an unknown cause, six months after his operation. Another succumbed to lardaceous disease secondary to a pyo-pneumothorax, which was infected with pyogenic organisms. The remainder died from tuberculosis slowly progressing in the uncollapsed lung.

II—FROM THE POINT OF VIEW OF THE PHYSICIAN *

BY

F. G. CHANDLER, M.A., M.D. Cantab.,
F.R.C.P. Lond.

Physician with charge of Out-patients, Charing Cross Hospital
Physician City of London Chest Hospital, Victoria Park.

WHEN I was asked to open this discussion from the physician's point of view I began to formulate to myself what exactly is the difference between the physician's and the surgeon's point of view, for different they undoubtedly are. The notion of the surgeon as a blood-thirsty empirical monster itching to use the knife would be, to-day, a ludicrous travesty as far removed from the truth as certain notorious writers' ideas about scientific medicine. So it is with the conception of the physician as an old

woman brooding over cases until it is too late, and whose only theatre of active operation is the autopsy chamber. The surgeon is a man of action, his is the bolder mind. He will say that if there is the slightest chance of doing good he should act. With the physician or the general practitioner, however, lies the initial responsibility. It is to him that the patient comes first for advice. In recommending a serious surgical operation he takes a great vicarious burden upon himself. He has to consider not only that an operation may do good and the probability of cure or marked amelioration, but the possibility in some cases that a severe ordeal may be endured with no amelioration, or even with a worsening of the patient's condition.

The surgeon's relationship to his patient is usually more impersonal. The mental and physical strain imposed by operation and the possibility of post-operative complications are sometimes belittled. When the patient returns to his bed with a good colour, free from shock, free from pain, and the wound heals by first intention, the surgeon may justly congratulate himself on the immediate success of his performance. Yet, though the operation has been a masterpiece of technical skill and dexterity, it will mean little to the patient or his doctor if the desired result is not achieved. Though the surgical skill will receive recognition, it is to us that the patient will come with reproaches. The physician cannot help considering the operative risk, the possibility of after-pain and discomfort, particularly in chest surgery. His concern too is with the ultimate result, not the effect on the lung operated on, but on the patient's general condition. There is another more subtle factor in the surgeon's decision. He has his own credit to consider. His results when published will be criticized. His mortality figures cannot fail to be regarded as a reflection on his skill. In a bad case he will realize that in tackling it he will run the risk of increasing his mortality figures. In my experience this reasoning has not affected his decision. On the contrary he is apt to say that if operation gives the patient the slightest chance he must consider the patient and not his own reputation. Thus the very generosity of his outlook will tend to subject the patient to operation in cases where the physician will feel very doubtful of its advisability and where the patient if he knew the risk, might prefer to die. So grave is the decision in some cases, so uncertain the prospect that the patient must be taken into our fullest confidence and sometimes decide the question for himself. In major chest surgery there are peculiar difficulties. There are problems of judgement as well as of technical skill. If it were possible a combination of the physician-surgeon would be ideal. Ordinarily such a combination would be impossible. But, fortunately, in thoracic surgery, owing to peculiar circumstances, we have had this combination, and it is to physician surgeons—if I may so designate them—such as Saugman, Morrison Davies, Gravesen, Jacobson, and others, that we owe not a little in the development of the procedures under discussion.

PROCEDURES

The procedures that I propose to discuss are (1) The open operation for dividing pleural adhesions in artificial pneumothorax—so-called "intrapleural pneumolysis" (2) Phrenic evulsion (3) Apicolysis and pneumolysis (4) Thoracoplasty (5) Oleothorax. These procedures I will discuss from the standpoints of (1) immediate risks, (2) after-pain and distress, (3) ultimate results.

1 The Open Operation for Dividing Pleural Adhesions in Artificial Pneumothorax—So-called "Intrapleural Pneumolysis"

This method, unfortunately, has not been successful, the pleural cavity becomes septic. Why this should be so I do not know. If care be taken not to divide adhesions containing lung tissue, if the cautery and this alone is employed, I cannot see why there should be any septic complication. Glove has shown that adhesions devoid of lung tissue may yet contain giant-cell systems, but, even so, with the cautery this should not cause trouble. It may not always be possible to know if lung tissue is

present in an adhesion, and if traction of short adhesions is employed the lung may be torn. But, whatever the reason, the fact remains that the operation has not established itself, and those few cases that I have seen have developed empyema. There is little disturbance from the operation itself.

2 Phrenic Evulsion

The immediate risk is small, but haemorrhage, haemoptysis, an embolism, chylous fistula, and injury to other nerves have been reported, among my own cases there was one death from pulmonary oedema four hours after the operation, under general anaesthesia, and in one case what may be called a chylocele developed, owing to injury to the thoracic duct. But such events are very rare. After-pain and distress are slight—the patient can often walk about the day after the operation.

From the operation there may be marked benefit. If not, the procedure has been slight, the ordeal small, and it is an excellent preliminary to the methods about to be described. Morrison Davies will, I trust, give us the results of his own large experience, but I may perhaps be allowed to quote from his conclusions¹.

He is of the opinion, and I agree, that in cases of lusal tuberculosis it has been unquestionably of immense assistance in arresting the disease. Benefit may be obtained in more generalized disease, and when used as an accessory to incomplete artificial pneumothorax. It will certainly relieve distressing cough and pain in some cases, and at the termination of an artificial pneumothorax, when the lung cannot expand and much mediastinal displacement is occurring, it is of undoubted benefit.

3 Apicolysis and Pneumolysis

From the physician's point of view these are the operations of choice. There is little or no shock, little discomfort afterwards, and the operative mortality, so far as I know, is negligible. Unfortunately, however, no satisfactory packing substance is known. Fat and plastic paraffin are most commonly employed, but both are apt to be extruded little by little through a pinhole sinus. Nevertheless, though this befalls, an apical cavity may remain closed, with its walls adherent. I personally am greatly interested in and impressed by the possibilities of this operation.

4 Thoracoplasty

It is the operation known as thoracoplasty that presents the greatest problem in this discussion. I have seen the most brilliant and lasting results from the operation, and I have seen the reverse. It demands the most perfect technique, the most complete understanding, and the most exact comprehension of what is to be achieved. It is not an operation that any surgeon can do, nor is it, in my opinion, justifiable to undertake it without an apprenticeship. I feel that after-results cannot be usefully discussed without a clear idea of the criteria of suitability and non-suitability.

Types of Cases Suitable

- 1 If a successful artificial pneumothorax has been allowed to terminate with a recurrence of symptoms and re-collapse is not possible.
- 2 If an artificial pneumothorax is imperatively indicated in a case of progressive unilateral disease, yet by reason of adhesions it is not possible to induce one.
- 3 If chronic unilateral disease is present causing distressing symptoms—excessive expectoration, recurrent haemoptysis, fever, inability to work, etc.
- 4 A tuberculous empyema, if producing symptoms.

Types Not Suitable

- If in the other lung there is a suspicion of active or progressive disease.
 - If resistance is poor, judged by personal history, coarse, and family history.
 - If the condition is one of fibroid phthisis with every prospect of many years of reasonably healthy life.
 - If amyloid disease or severe tuberculous ulceration of the intestines exists.
- The operation has been done some two or three thousand times at least. The results are published so that we

can form a fair estimate of the immediate mortality and the after-results. For example, Dr Gravesen, who has very kindly sent me particulars of his cases up to the present time, had in the first 100 cases a mortality of 9 per cent, in his subsequent cases a mortality of 4.9 per cent. The results have improved with increasing experience. Taking it all round we may assume an immediate operative mortality from about 5 to 12 per cent. John Alexander of Michigan University, in his encyclopaedia book on the *Surgery of Pulmonary Tuberculosis*, has collected 1,159 cases in which the operative mortality was 13.2 per cent. But these figures include cases operated on in the early days and different types of thoracoplasty.

The after-pain and distress within the first few days after the operation vary enormously in different cases. In some instances there is undoubtedly great pain and distress and profound shock, in others very little. J. E. H. Roberts claims that after-pain may be prevented or minimized if the peritoneum is stripped with great care so as to avoid unnecessary injury to the intercostal nerves, and if the muscles are not lacerated. The wound sometimes becomes boggy and sometimes septic. Aichwald claims that this may be prevented by avoiding the use of large quantities of local anaesthetic. Aspiration pneumonia may occur, but this can, to some extent, be minimized by careful anaesthesia and by not completely abolishing the cough reflex after the operation by anodynes.

Of cures, Dr Gravesen's most recent figures show 42.5 per cent out of 155 cases fit for work at the present time, more than two years after the operation. Whereas of those not operated upon and in whom extensive or universal adhesions prevented an artificial pneumothorax, only 11 per cent were fit for work. These cases are comparable with those operated upon, for it is from this class that those for operation are selected.

Of Alexander's 1,159 collected cases, 42 per cent were cured or greatly improved. Recent experience has been more favourable both as regards mortality and results. As Gravesen says, it is encouraging to see that thoracoplasty improves the prognosis from 10 or 12 per cent to 40 per cent of cures. I think we must regard such an experience as very good, seeing that the patients operated on have a serious disease in an extensive form, and who, in most cases, have been ill for a long time.

There is surprisingly little deformity to the outward eye after the operation when the patient is dressed. In a good case the patient can use the arm on the side operated on even to doing manual work or playing tennis.

To sum up, I would say that if the case comes strictly within the criteria mentioned above, the possibility of surgical cure should be put to the patient, that while we cannot guarantee the result, there is a prospect of complete and permanent recovery, and that such treatment is the only effective method we have, at the present time, of bringing this to pass in this type of case.

5 Oleothorax

I feel that a reference to this is justified, although our experience of the method is still limited, because of its extreme simplicity and because it may prevent the need of a thoracoplasty. Obliterative pleurisy is one of the most serious complications of artificial pneumothorax. Once well started, no amount of air pressure will keep the pleural layers apart. Little by little, with invincible force, the tentacles of contracting fibrous tissue draw the pleural layers together from below upwards. By inducing an oleothorax I believe this process may be stayed. The oil is driven to the upper part of the chest and then the space can be contracted no further and it is usually just this upper part that we want collapsed. In this way a condition which might render thoracoplasty necessary may be prevented.

In conclusion, I would say that there is still an apathy towards modern advances in the treatment of pulmonary tuberculosis. Patients not doing well are frequently allowed to go on with no special treatment and to pass the stage where artificial pneumothorax might save the situation.

RADIUM THERAPY OF CARCINOMA OF THE CERVIX UTERI*

AN ANALYSIS OF RESULTS OBTAINED AT THE WOMAN'S HOSPITAL, NEW YORK

BY

GEORGE GRAY WARD, M.D., F.A.C.S.,

Professor of Gynaecology and Obstetrics, Cornell University,
Chief Surgeon, Woman's Hospital, New York

I HAVE no apology to offer for having the temerity to bring to your attention this subject, as the therapy of cancer of the uterus is by no means accepted and standardized as are most of our gynaecological problems, and because the literature is full of conflicting opinions as to the results obtained, and as to what is the most efficient technique. Therefore, in the hope that our few drops of clinical experience in the radium therapy of carcinoma uteri during the past ten years at the Woman's Hospital in New York may act as a reagent to help clarify the hazy mixture of the various clinical reports, I beg leave to give you a survey of our observations and viewpoint as a small contribution towards bringing about the stabilization of the therapy which I am sure we all ardently desire.

Before the discovery of radium by Mme Curie the treatment of cancer of the cervix uteri was by local destruction of the carcinomatous tissue with some form of cauterization or by operation. The technique of the radical operation, as developed by Wertheim, gave so much better results than other operative procedures that up to the last ten years practically no other treatment has been used. The question to-day before us is, Can we with radium obtain the same result in treating cancer of the cervix as can be obtained by the Wertheim operation without its high primary mortality? No one questions the palliative effect of radium in the inoperable cases of carcinoma of the cervix, but to ascertain the true value of irradiation one must compare the results by operation with the results by irradiation in operable cases of carcinoma of the cervix uteri.

At this time there are only a few large clinics using radium alone for operable cases of cancer of the cervix, and consequently only a few series of operable cases of carcinoma of the cervix treated with radium five years or more ago to compare with the large number of cases operated upon radically and observed for a period of five years or longer. The object of this paper is, therefore, not only to report the results obtained in the Woman's Hospital of New York by irradiation of all cases of cancer of the cervix, but especially to show our results by irradiation of operable cases in the ten years that we have had radium in the hospital.

In the past year two statistical studies on surgical and radiological treatment of cancer of the cervix uteri, of great importance to physicians concerned directly or indirectly with this disease, have been published—one in England and one in Sweden. The first study mentioned is an exhaustive report by Dr Janet E. Lane-Claydon, published by the Ministry of Health in England and based on the data published in sixteen different countries relating to the records of some 80,000 cases of cancer of the uterus treated by operation or radium. This is a work of great magnitude, and includes a most valuable bibliography. The second study is a comparative analysis by Heyman of the Radium Hemmet in Stockholm, which he presented before the Scandinavian Surgical Society at Gothenburg in June, 1927. This is an admirable review and comparison of the published statistics of the results obtained in twenty surgical clinics and seventeen radiological clinics in Europe and America in operative or radium therapy of carcinoma of the cervix uteri.

In his comparative study of published statistics Heyman has reduced the figures of all the clinics to one uniform standard. He has left out all doubtful statistics and does not deduct intercurrent deaths or non traced cases, and

quotes only the accepted five-year cure. His combined summary of twenty surgical clinics and seventeen radiological clinics shows

For total cases—			
Operative treatment	approximately	18.0	per cent
Radiological treatment		16.3	
For operable and borderline cases—			
Operative treatment		35.6	
Radiological treatment		34.9	
Primary mortality—			
Operative treatment		17.2	
Radiological treatment	less than	2.0	
Operability—			
Operative treatment		43.0	
Radiological treatment	less than	30.0	

While these figures apparently approach each other very closely it must be evident that it is not fair to consider them as similar when we take into account the great difference in the character of the initial material as shown by a 43 per cent operability in the operative statistics as compared with less than 30 per cent in the radiological figures.

The above general averages are interesting when compared with the results obtained at the Radium-Hemmet at Stockholm by Forsell and Heyman. From 1914 to 1921 inclusive they reported for all cases 22.4 per cent free from symptoms after five years, and borderline cases with a five-year cure of 44.4 per cent. Their primary mortality from irradiation was 1.59 per cent.

These results, contrasted with the general average of the operative treatment, are certainly to the advantage of irradiation therapy, especially when we consider the character of the initial material from which these figures are compiled.

TECHNIQUE AT THE WOMAN'S HOSPITAL CLINIC, NEW YORK

We have not a large amount of radium at our disposal at the Woman's Hospital, New York. Our armamentarium consists of some 280 milligrams of the salt in tubes and needles, and our average initial dosage has been from 2,400 to 4,200 milligram hours. It is of interest to note that the Radium-Hemmet at Stockholm also uses the salt in similar dosage, and does not use the emanation with massive amounts. Our experience convinces us that the employment of massive doses cannot show any better results than the intelligent application and reapplication of smaller doses.

We start with the principle that every case of cancer of the cervix is a study in itself, and that the frequent personal observation by the surgeon directing the treatment is absolutely essential to obtain results, and this personal contact must continue throughout the period of cure. As we cannot say when any case is permanently cured, this means the patient should be under observation at regular monthly intervals throughout her life, if she would be safe, as we believe we have obtained our results by this constant watching enabling us to discover a recrudescence of the disease in its early stages long before the patient would be aware of symptoms. Thus we have the opportunity of putting out the fire while it is yet a small blaze by prompt re-radiation, instead of having to try and extinguish the serious conflagration which would be present when the patient had developed symptoms. If there is an opportunity to plant a radium needle in a suspicious area at the onset of a recurrence the problem is much simpler, as the chances of smothering the fire in its inception are greater. We therefore believe in repeated re-radiations as often as indicated, 50 per cent of our cases have had more than one application, and many of our successful cases have had three or more irradiations. It is upon this personal frequent follow-up of our cases that we have based our treatment, and attribute to it whatever success we have had.

As we are familiar with what the post-radiation picture should be at the end of each month, we think we can tell from the general appearance of the growth whether the several stages of hyperaemia, local sloughing, separation of the slough, and healing process with final cicatrization and marked contraction, which represent the phenomena

* Read in the Section of Obstetrics and Gynaecology of the Annual Meeting of the British Medical Association, Cardiff, 1928.

of irradiation of the cervix by radium, are progressing satisfactorily. This process, as we have observed it at our clinic, has been graphically shown in a paper published by Farrar. Our technique of application is simple and has been described in a previous report. We employ brass and rubber screening of the radium tube and distance screening with vaginal gauze for the protection of the bladder and rectum. We believe anchoring of the radium tube by suture is an important detail. We prefer the short needles to the long model for implantation in the periphery of the growth, and we believe the needles should not be closer to each other than 2 centimetres. Usually four needles are sufficient, unless the growth is very large. We have found a self-retaining catheter inserted in the bladder during the time of the radium application is most satisfactory to all concerned.

Many of these patients are suffering from toxic absorption and are cachectic and anæmic. During the sloughing stage of the radiation process there is necessarily an increased absorption of these toxins with resulting septic fever and an increase of the debilitated state. We have found that blood transfusion is an important adjunct to the irradiation in enabling these patients to combat this sepsis more successfully. Wherever possible we give these cases 500 c cm of blood before their discharge from the hospital.

Important details are to get the patient up early to favour drainage, and to give careful instructions as to repeated daily douches of potassium permanganate solution to favour separation of the slough, to deodorize it, and to stimulate tissue growth.

Our results have been obtained without the employment of high voltage x-ray therapy as an adjunct, as we have not the apparatus, and our employment of a moderate voltage as a post-radium treatment in some of our cases seemed harmful, and gave us less satisfactory results than when we used radium alone. So for the present we do not use x-ray therapy in conjunction with radium as a routine. We believe, however, that high voltage attack on the lymphatic glands to produce a lymphatic block as an adjunct to radium therapy is theoretically correct, and if it can be done without associated injury to the adjacent viscera it would be ideal.

Each patient is requested to report once a month in the follow-up clinic. Dr Farrar and myself attend this clinic in person, and one or the other of us palpates and inspects each cervix with its adjacent tissues.

PROGNOSIS FROM THE TYPE OF CELL

In view of the interest that has been aroused by Martzloff, Cutler, and others on the possibility of making a prognosis as to the probable reaction to irradiation in accordance with the predominating type of cell in cervical carcinoma, I have had Dr Plaut, our pathologist, study the type of cell in our series. We have not found it possible to predict the result from the type of cancer cell, for we have observed when several pieces of tissue have been taken from different places in the growth that different types of cancer cells are present. While we hope that the grading of the type of cell may prove to be as reliable an index of prognosis as some pathologists expect, still we are inclined to believe with Dr Plaut that there is at present a bewildering mass of contradictory evidence as to its value.

In 1925 we reported our results at the Woman's Hospital in New York of two five-year series of radium therapy for carcinoma of the cervix before the American Medical Association. Our percentage of cures of all cases was 23.6, and for the early and borderline (operable) cases it was 52.9, based on cases traced, or 22.4 and 50 when including the non-traced cases, to accord with Heyman's uniform standard, with a mortality of 1.6 per cent. Since that date we have completed two more five-year series, and are now able to report on all cases treated in 1919, 1920, 1921, and 1922, and the first five months of 1923. Our records and follow-up end-result cards have been audited by professional statisticians, and the figures I present to you have been compiled by them and certified as correct.

It has seemed well before giving our statistics to state definitely the character of the cases we are reporting. We have included only cases of carcinoma that have originated in the cervix and have not been operated upon or treated with radium elsewhere, so that we may compare our method of radium treatment with the radical operative treatment in similar classes of carcinoma of the cervix uteri.

TABLE I.—Primary Carcinoma of the Cervix Uteri. Radium Five Year End Results

Gynaecological Service Woman's Hospital May 1928

	Treated	Traced	Living	Percentage Living	
				Cases traced.	Cases treated
Classes 1 2 3 4	134	126	31	24.6	23.1
Classes 1 and 2 (limited to cervix)	32	30	17	56.7	53.1

Primary mortality 0.44 per cent.

Comparing these results with the statistics of seventeen clinics as given by Heyman in his report, and also with the results obtained by Forsell and Heyman at the Radium-Hemmet in Stockholm, we have as follows:

TABLE II.—Comparative Results of Radical Operative and Radiological Treatment of Carcinoma of the Cervix (Five Years)

TOTAL CASES TREATED

*All Clinics	Per cent.
Operative treatment	18.0
Radiological treatment	16.3
*Radium Hemmet	22.4
Woman's Hospital Clinic, May, 1928	23.1
Primary Mortality	
Radical operation	17.2
Radiological treatment	2.0

*From Heyman's Report, 1927

TABLE III.—Operable Cases (Five Years)

*All Clinics	Per cent
Operative treatment	35.6
Radiological treatment	34.9
*Radium Hemmet	44.4
Woman's Hospital Clinic May 1928	53.1

*From Heyman's Report 1927

Although our total series is small as compared with the Radium-Hemmet, still it is encouraging to know that our last two five-year series maintain the percentages achieved in our previous report. It must be borne in mind that the percentages given for the borderline cases must always be of uncertain value, as "borderline" means confusion, because it must depend entirely upon the personal equation of the surgeon, and we are inclined to agree with Jeff Miller that it is a useless classification for practical purposes, and that we should simplify our statistics by having only two types—early and advanced. Likewise there must be uncertainty as to the term "operability," because one surgeon will consider operable, and will operate on, cases with definite involvement of the parametrial tissues—as, for instance, Victor Bonney—while many of us who are conservative will not consider a case operable unless the uterus is mobile and without infiltration beyond the cervix. Consequently the figures given for "operable" cases will always be of unstable value for comparison also.

The lack of standardization of statistical reports is what complicates the problem of making fair comparisons. A cursory glance at the various reports published in the literature will show what a great variability exists in presenting the subject. Two-, three-, and four-year results only add to the confusion, and should be abandoned. Only five-year observations should be considered.

In giving the report of our cases of carcinoma of the cervix treated with radium we have felt the need of standardization of statistics, and would urge that we have—

1. A uniform classification of the growth itself. Schmitz's classification of groups from I to IV gives a sufficiently definite anatomical description of the extent of the tumour itself, and this grouping we have adopted in our work.

2 The report of only five year results—total cases and early cases. For comparison with the operative results obtained, we must take the same period that surgical clinics do—that is, five years.

3 Inclusion in statistics of all patients that either have not been traced or are dead from any cause as *dead from cancer*. This may seem unfair in some instances where it is difficult to trace cases, or in hospitals that do not have a follow up, but if the rule applies to everyone it can only affect a small percentage of cases and may lead to a better follow up system. Heyman, in his statistical analysis of over 8000 cases, has followed this procedure.

4 Operability rate and primary mortality. These should be given for comparison with cases treated by radical operation.

PROPHYLAXIS

The role of chronic irritation as an etiological factor in the development of carcinoma makes it imperative that lacerations and erosions of the cervix should not be neglected. In a study by Farrar of 300 consecutive case histories of cancer of the cervix at the Woman's Hospital in New York it was found that pregnancy had occurred in 96 per cent. In 288 cases 11.1 per cent of the patients had had the last pregnancy less than five years and 20.3 per cent less than ten years before entering the hospital for the malignancy. We believe that the immediate repair of cervical lacerations, when done under proper conditions as in a hospital, will lessen the danger of subsequent development of carcinoma in the cervix.

CONCLUSIONS

In conclusion, I wish to draw attention to the following creed which I hold.

There is less primary mortality, less morbidity, less loss of time with radium therapy than in the radical operation for carcinoma of the cervix.

The palliative results in cases not permanently cured are an important advantage not to be ignored.

The morbidity results of the radical operation—fistulae, thrombosis, suppuration, etc.—are not to be forgotten.

Vesical and rectal fistulae should be increasingly less frequent in radium therapy as the technique develops.

Repeated irradiations are of distinct value, and subsequent treatments should be based on the reaction to the initial or test dose.

A personal monthly inspection or follow-up is an essential throughout the period of observation, in order that by a watchful waiting we may discover a recurrence in its incipency and thus extinguish the fire before it has gained headway.

Large amounts of radium are not necessary to produce results.

A standardization of statistical reports on irradiation of cancer of the cervix is needed for comparison of results in different clinics.

We believe that our results show that radium is preferable in all classes of cervical carcinoma. We also believe that in the very early cases the radical operation will give the same result as radium, but at the cost of high primary mortality and greater morbidity.

As to the early cases—and how few we see!—with the present statistical figures available it is not yet proved which gives the best results, but the available figures do not show that the operation is any better than radium.

RADIUM IN THE TREATMENT OF CARCINOMA CERVICIS AND INTRACTABLE MENORRHAGIA *

BY

J. FARQUHAR MURRAY, M.D., F.R.C.S.,
Lecturer in Midwifery and Gynaecology University of Durham

CARCINOMA CERVICIS

THESE observations are based on a study of over 200 cases treated with radium since January, 1926, and an experience of 130 radical operations (Wertheim). All the cases were checked by pathological report.

Radium bromide (100 mg) was applied for twenty-four hours to the external os, if it was ulcerated, or into a crateriform cavity if one existed. In a few cases 200 mg was used. After the application the patient rested for fourteen days, took potassium iodide, 5 grains thrice daily, and had a douche every day.

Pathology

Forty-five uteri which had been exposed to radium and had been reported to be malignant were sent for a further report after removal. Radium had been applied at least fourteen days previously, and in some cases one or two months had elapsed. Nine reports, when referring to the malignant growth, contained such terms as "disorganized," "retrogressing," "some necrosis," "being plagiocytosed," and three stated that there was no evidence of malignancy. In the remaining thirty-three uteri the malignant cells were apparently unaltered.

Radium applied directly to the growth can produce a beneficial result, but my operative experience makes me doubt its practical value in dealing with glandular deposits.

In order to appreciate the results the terms "operable," "borderline," and "inoperable" must be defined. These are based on the local condition as judged by the possibilities of the radical operation (Wertheim) and without reference to the age or general condition of the patient. For the benefit of those who are not conversant with operative technique it might be useful to state that the radical operation entails removal of a cuff of vagina with the cervix, as well as the extirpation of the lymphatic glands. An ordinary total hysterectomy, sometimes called panhysterectomy, does not allow of this.

Operable means that the growth is limited to the cervix, or has involved the vagina only to a limited extent, and that there is little, if any, infiltration of the cellular tissue.

Inoperable implies (1) that the ulcer extends so far down the vagina or into the broad ligaments as to prevent removal or (2) that the cellular tissue in the ligaments or round the cervix is densely infiltrated.

Borderline refers to the intermediate cases. This classification will, to some extent, depend upon the individual operator.

1 Operable Cases

In 20 cases considered operable prior to January, 1928, radium alone was used. These cases were not submitted to operation owing to such causes as age, general condition of the patient, or the presence of heart disease or diabetes, in two cases operation was refused, and in two others the application of radium made the condition clinically inoperable.

Results

Excluding two cases which have been lost trace of, the after-history of the 18 at the present date is as follows:

Improved	3
Stationary	3
Worse or dying	6
Dead	6

* Read at the Annual Meeting of the British Medical Association (Section of Obstetrics and Gynaecology) Cardiff 1928.

I do not now use radium as a routine prior to operation, since in several instances it appeared to make the local condition worse and even inoperable, while the operation area is certainly made more vascular if it has been applied recently. It should be used if the ulcer is spreading on to the vagina and there is some surrounding infiltration. A ureter can be dissected out of an infiltrated area, but, if the infiltration is due to malignancy, I am satisfied from histological reports that the only chance of success lies in devitalizing the malignant cells by radiation prior to operation.

I compared the after-results of 38 operable cases which had the radical operation alone with a similar number which had the radical operation after a preliminary application of radium. At the time of making the record a minimum of three years had elapsed in the purely operative group, and of one year in the radium group. The results are as follows:

Operation only	Per cent.
Alive and well	60
Operative deaths	5
Recurrence	30
Death from other causes	5
Radium and operation	
Alive and well	44
Operative deaths	16
Recurrence	34
Death from other causes	6

These results appear most unfavourable to radium, but the correct interpretation of them, in my opinion, is that by the use of radium it is now possible to include in the "operable" group cases which, in earlier days, one would have hesitated to operate on. It does not alter my opinion, however, that the preliminary use of radium, even in an early case, increases the operative risk and that in some cases it appears to aggravate the condition.

2 Borderline Cases

These require particular discrimination. Radium may improve the local condition and render a previously fixed and ulcerated cervix mobile and smooth, but this improvement may be more apparent than real so far as ultimate operative treatment is concerned. Ulceration may be inhibited, but tissues which have been destroyed can never be replaced, and from time to time I have regretted disturbing the scar tissue which followed an application of radium, the bladder has been opened, or the cervix has torn during the operation.

3 Inoperable Cases

In these cases radium undoubtedly improves the local condition. There is usually a smoothing and ultimately contraction of the ulcerated area, and not infrequently a diminution in the secondary infiltration. The patient reports that she feels better, and that the bleeding, and even the discharge, has ceased. The actual duration of life does not appear to be very greatly influenced in the majority of cases.

Of 23 cases considered inoperable in 1926, and treated by radium alone, 4 are alive in July, 1928, but 3 of these are going downhill. The one exception shows no evidence of growth after eighteen months. This was a case of extremely superficial ulceration spreading down the vagina to the urethra, which rapidly disappeared after one application for twenty-four hours of 200 mg of radium bromide.

Five cases seen in 1926, and considered inoperable, were so improved after radiation that the radical operation was performed. Of these, 2 died shortly after operation, 1 survived operation and lived thirteen months, and 2 are alive and well to-day and with no evidence of recurrence.

The after-history of 24 inoperable cases seen in 1927 is as follows: 17 are already dead, 5 are dying, and 2 show no definite change.

I am convinced that radium is invaluable in dealing with this condition, and that, in certain cases, it can produce results little short of miraculous. It is certainly the only treatment of proved value which can be used in the majority of cases met with, and undoubtedly produces beneficial results in most cases. I am equally convinced that it has not superseded the radical operation when such is possible. Its use is specially indicated in elderly women in the late fifties, as the growth appears to be particularly responsive to radiation.

Menorrhagia

Fifty-five cases treated with radium have given most encouraging results. A multipara in her forties, whose heavy losses will not respond to diags or curettings, and who would otherwise have her uterus removed, is a typical case justifying this treatment. The advantage of effecting a cure without resort to the major operation is obvious.

After excluding malignancy and pelvic inflammatory trouble the uterus is dilated, vigorously curetted and irrigated, and 100 mg of radium bromide is inserted for twenty-four hours into the uterine cavity. The radium is tied in the distal portion of a rubber tube, the proximal end of which lies in the vagina to allow of easy extraction. The vagina is lightly packed with gauze. After removal the patient rests for fourteen days and keeps her bowels regular. Apart from slight sickness during treatment nothing untoward is noticed.

The usual after-result is the establishment of the menopause at once, or after a few weeks, during which the patient notices a slight brown discharge. In one instance the patient's doctor reported that a pelvic abscess had discharged after her return home.

Results

Thirty-seven patients aged 40 and over were treated, all except 4 having had one or more pregnancies. All, with one or two exceptions, had been curetted on one or more occasions. Of the 37, 9 must be excluded, as they have been too recently under treatment, but reports indicate that they are in process of being cured. Among the remaining 28 there were 27 complete cures, the failure was an early case and due to faulty technique, and would almost certainly have responded to a second application. While 40 is a convenient milestone, younger patients were met with who gave a similar history prior to being treated.

In a series of 14 patients, 3 of whom were in their late twenties and had been curetted three to five times, 11 were cured. Of the remainder 1 is too recent to record, and the 2 failures were due, in my opinion, to faulty technique, the radium in one case being inserted into the cervical canal, and in the other the uterus had not been curetted prior to the application.

Four patients were treated who had small fibroids varying in size from a walnut to a golf ball. In 3 of these amenorrhoea was produced, but the fourth was a failure due to the subsequent extrusion of a submucous fibroid. One of the 3 apparent successes has since shown signs of degenerative changes taking place in the fibroids.

Conclusions

Radium treatment is safer, and almost as certain in its results as hysterectomy, and is the preferable form of treatment in such cases. The advantage to the patient in every respect must be obvious. It is specially indicated in patients suffering from disease of the heart, lungs, or kidneys, where a long anaesthetic and major operation should be avoided and a cure must be certain. It is also the ideal treatment in extremely nervous and elderly patients. Its use in cases complicated by small fibroids would only be justified by the general conditions already mentioned, and not as a routine procedure.

Radium might be of use in producing the artificial menopause in patients suffering from pathological blood disease, with a view to conserving their blood supply.

MEDICAL, SURGICAL, OBSTETRICAL.

SUBCUTANEOUS RUPTURE OF THE PECTORALIS MAJOR MUSCLE

The following case appears to be sufficiently unusual to warrant putting on record

A well-developed muscular youth, aged 19 was admitted to the Queen Alexandra Military Hospital London on May 9th. He gave a history that on the previous evening, while engaged in the second round of a boxing contest, he felt a sharp pain in the front of the right side of his chest. He was able to finish the round and boxed the next and final round without much discomfort. On retiring to the dressing room he noticed a swelling in the anterior wall of the right axilla. From the time it was first noticed the swelling did not increase in size except when the pectoralis muscle was contracted. On examination an area of ecchymosis was seen, extending along the lower part of the pectoralis major from the arm to the chest wall. Towards the outer edge of the anterior axillary fold a soft mass was palpable. On contracting the muscle some discomfort was complained of and the mass became harder and more prominent. At the same time a well marked notch was visible below and internal to the swelling as shown in the photograph. This notch was tender on palpation. The patient was quite unable to give any account of what he was doing with his right arm at the moment he first

felt the pain. He was, however, quite definite that he had not at any time been struck on the chest by his opponent. A diagnosis of partial rupture of the pectoralis major was made. Two days later the lower edge of the pectoralis major was exposed by turning down a skin flap. At first sight the muscle, in the relaxed condition appeared to be uninjured owing to the fact that the fascia over it was intact. On passing a finger under the axillary fold, however, a rent could be felt in the muscle, which extended upwards and inwards from its lower border for a distance of about two inches. The fascia on the deep surface of the muscle was also torn. The ruptured muscle, which appeared to be quite healthy, was sutured with chromicized catgut, and the arm was bandaged to the side. The patient made an untroubled recovery and no apparent weakness of the arm resulted.

The chief interest of the case lies in its rarity. To produce such a lesion the muscle must have been violently contracted while on the stretch. In surgical literature I have only been able to find reference to five cases. Mandl records a case, which occurred in a gymnast who, while swinging on rings, was attempting to rotate his body in its long axis through 360°, felt a sharp pain in the chest, and was unable to complete the exercise. The patient was seen one and a half years after the accident and a condition similar to that described above was found. The muscle had not been sutured and some weakness of the arm persisted. Mandl mentions having been able to find records of three similar cases in current literature, all of which occurred in well-developed muscular subjects during the performance of gymnastic exercises. Fisselsberg mentions having seen one case in the Billroth Clinic, in which the patient was admitted with a suppurating haematoma following a partial rupture of the pectoralis major.

TRAUMATIC SEPARATION OF AN INTESTINAL LOOP

The complete separation of a loop of small intestine in the absence of a penetrating abdominal injury must be a very rare occurrence. The following details of such a case seem, therefore, to be worthy of record.

A Hindu man aged 60, was admitted to the surgical wards of the Madras General Hospital with a history of having been knocked down by a motor bus. He was almost moribund, the pulse rate being 80 and the respirations 22. There were some superficial injuries to the scalp and the lower jaw.

Two hours after admission the abdomen became distended and very tender. There was an inguinal hernia which was completely reduced with gurgling, but the process was painful. He vomited food about five times during the night, and passed a motion and flatus. He grew rapidly worse, and in spite of stimulants, died the next afternoon.

At the necropsy a number of superficial abrasions were found over both extremities, and there was fracture of the right ulna. On the right side of the scrotum was seen a large swelling the size of a child's head, which was soft boggy and oedematous. The skin over it was discoloured bluish, and peeling off. On incision it was found to be a hernia, and in the hernial sac was a piece of small intestine about 3 inches long lying loose with the mesentery cut close to it. The edges of this piece were sharp and regular, and the mucous membrane pale, without any evidence of inflammation. Just above this loose bit of intestine and in the hernial sac was another loop of small intestine. Between the sac and the skin was an abscess containing about 2 oz. of purulent fluid. The peritoneum was red and inflamed, the omentum was also inflamed and covered with flakes of lymph. There were about twenty ounces of turbid purulent blood stained fluid in the peritoneum. On carefully examining the intestines the detached portion was seen to have been situated about seven feet below the duodeno-jejunal flexure, it was pale and without any inflammatory reaction. The margins of the free ends of the small intestines showed redness and inflammation to a distance of about three-quarters of an inch.

It is of interest to note that the detached bit of intestine, having completely lost its blood supply, did not show evidence of inflammation, contrasting thus with the inflamed edges of the attached portions. It is extraordinary, also, how a complete detachment of a piece of intestine can take place without a penetrating abdominal injury, thus is of some medico-legal importance. What probably happened was that the man had an inguinal hernia and was hit over it by a sharp portion of the car, probably the mud-guard, a loop of intestine was caught between the car and the horizontal ramus of the pubis, and was detached.

Our thanks are due to Lieut.-Colonel E. W. C. Bradfield, I.M.S. Superintendent General Hospital for permitting the publication of this case and to Dr. S. K. Pillai, the radiologist for kindly taking the photograph of the specimen.

British Medical Association

CLINICAL AND SCIENTIFIC PROCEEDINGS

GLASGOW AND WEST OF SCOTLAND BRANCH

The Nature and Treatment of Asthma

At a meeting of the Glasgow and West of Scotland Branch of the British Medical Association on September 4th, with Dr. R. McNEIL BUCHANAN in the chair, Dr. BRUNTON HASSETTINE (Chicago) opened a discussion on asthma.

Dr. Haseltine, in the course of his interesting paper, said that the problem of asthma was particularly acute at the moment because of the prevailing pessimism which, especially in America, had followed the general disappointment with the results of the so-called allergy treatment. The conception of asthma which he was about to present differed considerably from those commonly held, but from the clinical point of view it had been shown to be considerably more successful. The conception was based upon the work of Drs. Brodie and Dixon of London, published in 1903, and the book on bronchial asthma by Dr. James Adam of Glasgow, which appeared in 1913. The first of these was a classic of scientific research, while the second was a clinical contribution of the utmost importance. Dr. Haseltine believed that if as much attention had been paid to these two contributions as had been given

to the theories of allergy and anaphylaxis, far better clinical results would have followed. The foundation of the present work was the recognition of the truth of Dr Adam's teaching that a toxic condition was the basic factor in asthma. It had been demonstrated that allergy itself was a symptom of this toxic state, and disappeared with its removal. The explanation of bronchospasm as a trigemino-vagal reflex was based on the well-known anatomical facts, and was accepted by all neuro-physiologists. Since it was known that the immediate inciting cause of the bronchospastic storm was usually a stimulus to the vagus from a peripheral source, considerable clinical assistance was provided in detecting and removing this cause. There was complete agreement in the evidence derived from five different considerations—namely (1) the close anatomical connexion between the fifth nerve and the vagus, (2) the experimental proof by Brodie and Dixon that bronchospasm was immediately produced by the irritation of certain intranasal areas, (3) anaesthetization of these areas checked the bronchospasm, (4) the finding that in asthmatic patients there were frequent pathological changes in these areas, and (5) correction of these conditions produced marked diminution and often cessation, of the bronchospasm. The degree of local tissue change or the amount of local irritation required to produce bronchospasm varied in different individuals, and in the same individual at different times. This variation corresponded closely with the variations in degree of the underlying toxic state. Thus, if an asthmatic patient had poor carbohydrate metabolism he was almost certain to suffer more from asthma after the ingestion of an excessive amount of sweets. With a poor gastro-intestinal function he had severe asthma when constipated, and was relieved by catharsis. If, again, he had a focus of infection, he was worse when drainage was poor, and obtained relief when an important focus was removed. By more careful methods of study it was possible to observe accurately these variations in the toxic condition and to control them very considerably, with corresponding clinical improvement. In addition to a thorough clinical examination of the patient, the blood chemistry was studied and quantitative urine analysis was performed frequently, the fluid intake being strictly regulated. By these measures it was possible to estimate with considerable accuracy the degree of toxicosis, and even to determine to some extent the relative importance of its various causative factors. Thus, if the urine analysis showed excessive acidosis, with possibly a high non-protein nitrogen content in the blood, the suspicion was aroused that the patient's toxic state was due to a bacterial cause, high eosinophilia indicated a chronic mucous membrane infection. If the urine showed an increased reducing power it was clear that toxicosis was due, at least in part, to faulty carbohydrate metabolism, if the ethereal sulphates were in excess intestinal fermentation was a factor. When endocrine dysfunction was demonstrated, either by clinical signs or metabolism tests, there was clearly an endocrine factor in the toxicosis, and an attempt was made to determine to what extent this dysfunction was causative and how far it was the result of infection. Dietary faults, when present, were corrected, but it was not necessary to restrict any patient's diet to the point of lowering general nutrition. This method contrasted strongly with the various starvation treatments for asthma which had occasionally been advocated. Almost any asthmatic patient would experience relief from spasm if all food was withdrawn for a time, Adam had shown in a striking manner the relation between overeating and toxæmia, especially in the case of the so-called "week-end" asthma in industrial workers. He combated this form of toxæmia by diet restrictions and the use of mercury at suitable intervals for a definite period. Some American physicians had had considerable success with the starvation treatment of detoxication, which was employed even in patients not considered to be overeating. It was obvious that the limitations of this method were very narrow, and it was dangerous in the case of patients of low vitality—a condition found in most sufferers from asthma. Dr Haseltine remarked that it was now possible to avoid both horns of the dilemma. Dietetic faults could be corrected and detoxication accomplished without impairing the

nutrition, the normal intestinal function could be re-established so that no mercurial or other purgatives were required at any time. The importance of allergic phenomena was fully appreciated, and careful watch was kept for clinical evidences of this condition. There had been many investigators in the field of allergy, and it was disappointing that the clinical results had been so meagre. Dr Haseltine differed from these investigators in regarding the allergy, not as a primary cause, but as one only of the manifestations of an underlying toxic state. All observers had noted that the degree of hypersensitiveness was subject to wide fluctuations in the same individual. It was remarkable that this fact had not suggested to any allergist that there might be discoverable, and perhaps removable, causes for these varying degrees of allergy; it had been shown that such causes were usually discoverable, and frequently removable, with resulting complete and lasting cure of the allergy. The importance of this difference was greater than was at first realized. It radically changed the conception of the problem, provided an entirely new line of approach, and enormously increased success in dealing with it. It was admitted that only about 50 per cent of asthma patients could be shown to be allergic, this automatically limited the use of anti-allergic treatment correspondingly. No such limitation existed for detoxication methods, because a toxic state could be demonstrated in nearly all asthma patients, whether allergic or not. Further, with successful methods of detoxication the allergic symptoms diminished, together with all other clinical manifestations. It thus became apparent why clinicians might become indifferent to the various substances to which the patient might be sensitive, if the underlying abnormality could be corrected, hypersensitiveness to all these substances could be removed. This could be accomplished in a higher percentage of cases than was claimed for any form of antigen treatment, and this result was in no case affected by the fact that previous antigen treatment had failed. In true bronchospasm there was, besides the general toxicosis, the factor of peripheral vagus irritation, and prognosis depended largely upon the extent to which this was discoverable and removable. In the beginning the irritation was nearly always nasal, and if correct treatment was given early the result was complete and lasting. No patient could undergo frequently the ordeal of bronchospasm without pathological changes developing in the bronchial mucosa. These might themselves be sufficient to incite the spasm, since the connexion with the vagus was direct. While this observation was self-evident, it was gratifying that spasm did not occur clinically so often as would be expected. In the majority of cases after the correction of nasal abnormalities the bronchial irritation ceased to be a troublesome factor. Indeed, the entire response, even of an old asthmatic case, to treatment along these lines was usually better than would be expected in view of the complex morbid anatomical conditions involved. With this conception of the problem it was unnecessary to treat asthma by the customary methods of trial and error. When the diagnostic study had been completed it became possible to foresee very closely the result obtainable in each case, and to outline the programme which would produce predicted results. This precision of prognosis for individual cases was not obtained by any other method of treatment. It had the double value of avoiding wasted effort and of preventing false hopes as to results, to the clinician confronted by the difficult asthma problem the value of this alone could hardly be overestimated.

Dr JAMES ADAM said that Dr Haseltine depended largely for his general detoxicating methods on his colleague Dr La Forge. Dr Adam had tried these methods, and concluded that those who viewed asthma as a toxicosis now realized that it was amenable to proper treatment. According as one or other factor predominated in any case, the asthma problem varied. In recent literature there was frequent reference to heredity and to anaphylaxis, but a regrettable lack of mention of toxæmia, which ought to be considered the chief factor. Asthma was a disease of civilization, and was largely "bought in shops." The man who had to hunt for his food and cook it before eating did not suffer from asthma, this was exemplified by the case of the Eskimos. Dr Adam stated that an

analysis of 1,000 of his own cases showed that there was a family history of asthma or kindred trouble in about 25 per cent, if heredity was the most important factor this percentage ought to be distinctly higher. Since asthma was essentially a disorder of disturbed metabolism it occurred especially during those years of childhood when the metabolism was being largely influenced for the remainder of life by the mode of upbringing and by infections. Dr Adam had found that in 40 per cent of his cases the condition began before the end of the 10th year, and in 50 per cent before the end of the 15th year. Infectious diseases and the immunity connected with them exercised a profound influence on metabolism. Several lantern slides were then exhibited by Dr Adam to indicate the influence of infection as modifying heredity in relation to asthma, and also to demonstrate the disturbance of the nitrogen partition in asthma as revealed by analyses of the blood and urine. In one case asthma began after whooping-cough at the age of 52, in another at 42, in another at 33, and, after scarlet fever in a fourth case, at the age of 48. The onset was ascribed to pneumonia in 8 per cent, the total incidence of pneumonia in asthmatics was 20 per cent. Dr Adam remarked that the first fifteen years of life was a period during which the child was being influenced for good or ill by his upbringing. That nurture accounted for more than nature as a factor in asthma was proved by the fact that, if there was no mouth breathing and no chest deformity, 80 per cent or more of these children could be freed from their asthma, no matter what the family history had been. The most difficult case was that of the only child spoilt by a hothouse upbringing. Dr Adam then gave further evidence of asthma being a toxicæmic condition, and remarked that, though in some asthmatics anaphylaxis might be blamed, yet some of these patients could be cured of their sensitiveness without resort to the injection of antigens. Dr Adam was convinced that the toxicæmia of asthma was accompanied by a tendency to acidosis, and that a fair index to this was the eosinophilia which occurred. Nasal treatment was certainly of more importance in asthma than was usually realized, the most satisfactory case to deal with was the asthmatic who had nasal polypi. Dr Adam then described the method of detoxication which he usually adopted, this included dieting, abundant open-air exercise, and a blue pill once or twice weekly, followed the next morning by a saline. The tendency to spasm was counteracted in the first six or eight weeks by potassium iodide and belladonna. Dramatic results sometimes followed the administration of 30-grain doses of baking soda until the urine was alkaline. Dr Adam then showed patients who had benefited by this line of treatment.

Dr HARRINGTON (North Shields) said that his treatment had followed the lines advocated, not one of his patients had so far failed to derive definite benefit. Even in the most extreme cases the La Forge procedure had resulted in dramatic benefit. He emphasized the importance of taking a careful history and making a complete physical examination, in which special attention was paid to the abdomen and nose. He considered the ingestion of water in large quantities to be of very great importance, milk in all its forms, except cream and junket, was eliminated from the diet. He regarded milk as being poisonous to an asthmatic, and frequently the cause of recurrent colds, bronchitis, and eczema. Dr Harrington added that he was quite convinced that every asthmatic patient had some derangement, other than the pulmonary, which required attention before success could be achieved.

Drs COLLIER and LANG contributed clinical illustrations of the treatment of asthma.

Dr J R MCCLARY (Cincinnati) said that he had himself been cured of asthma by Dr Haseltine. One of the most important points in treatment was restoration of normal physiological conditions. Asthma was due to a local and to a general disturbance of balance, and it was important to deal with the local factor.

The CHAIRMAN, summing up the discussion, emphasized the value of team work, and the benefit which a patient derived from different investigators collaborating in the investigation of his illness.

Reports of Societies.

MUSCLE AND TENDON SURGERY IN INFANTILE PARALYSIS

At a meeting of the Section of Orthopaedics of the Royal Society of Medicine on October 2nd, Mr NAUGHTON DUNN, the president, in place of the usual presidential address, opened a discussion on the surgery of the muscles and tendons in relation to infantile paralysis.

Mr Naughton Dunn said that all the principles on which orthopaedic surgeons relied in the treatment of infantile paralysis were on record, and he had nothing new to offer. The surgeon was rarely called upon to treat infantile paralysis from its acute onset right through to the final result, his common experience was to see the patient long after the initial stage had passed, when the child was unable to walk, or walked badly, and increasing deformity made the doctor and parents anxious. Two things were certain—namely, that the muscular control of the limb was already deficient, and that divided tendons and muscles quickly underwent further atrophy, so that shortening or deviation of a tendon or muscle for the correction of deformities in infantile paralysis should be resisted unless the surgeon was satisfied that such treatment was necessary for the correction of the deformity, and that there would be improvement of function. The prominence given to operative methods in the textbooks made him fear that there was some risk of the specialty becoming too surgical. In his own experience, extending over many years, he had seldom found necessary an operation for flexion contracture of the hip-joint resulting from infantile paralysis. He depended almost entirely upon the method of gradual correction of the deformity by splintage. With regard to tendon transplantation the literature was so confused that it was advisable to publish the methods which in the experience of an orthopaedic surgeon had proved successful. The history of this procedure did not differ from that of other surgical innovations like them, it had been practised by individuals, forgotten, and rediscovered more than once. It was now almost half a century since the operation was first utilized in infantile paralysis. Its growth in popularity had been spasmodic rather than steadily progressive. In recent years certain definite principles had been set up. Having decided that tendon transplantation was advisable to restore muscular balance, the question arose which tendon should be transplanted. Success or failure depended mainly on whether the transposed tendon would naturally or could easily be re-educated to perform its new function, also on the degree of tension under which the transposed tendon was sutured. It might be taken as an axiom of tendon transplantation in the lower extremity that a tendon or part of a tendon should only be used to replace one of its own group—that is, one normally in action with it. The re-education of the individual tendon to act apart from its group would appear to be more possible in the upper extremity. As to suturing, he himself sutured the tendons under considerable tension. Mr Dunn then discussed a number of typical cases with the aid of photographs and diagrams.

Mr T H OPENSHAW took up a remark of the opener, with which he agreed, with reference to the doubtful value of the transference of the biceps into the quadriceps. The speaker was unable to say when the quadriceps ought to be operated on and receive the transplant of any muscle. He had had at least a dozen cases in which splints had been worn for a number of years—from eight years up to twenty-three years (in the longest case of all)—with eventual recovery of power in the quadriceps. It could never be said that the quadriceps was not going to recover, provided, of course, that the patient was made to walk with instruments in the proper way, and the quadriceps muscle was exercised along the right lines of action.

Mr R C ELSLIE said that this subject was so difficult and diffuse that it was very necessary to arrive at certain general principles. The first principle was that the various methods of tackling these problems must be suitably combined. In every case a programme should be

drawn up indicating how it was proposed to utilize the methods of arthrodesis, tendon fixation, and tendon transplantation so as to get the best ultimate result. Looking at a deformed paralysed foot, for example, it was well to have a programme under these three headings: how to deal with the bones and joints, what to do in the way of fixing tendons, and what should be attempted in the way of transplanting. When dealing with the transference of tendons the anatomy had to be studied first, the proper alignment of the carried tendon, and its power to preserve function. A further principle was the physiological one: the tendon must be capable of re-education in its new function. There was a difference in this respect between the upper and lower limb, in the lower limb one was dealing very largely with the functions of locomotion, in which the actions were automatic or semi-automatic without obvious voluntary effort. Therefore it was necessary to be sure that the function of the transferred tendon was similarly automatic. In the upper limb the function was much more of a voluntary character, and re-education of voluntary action was more possible. The speaker feared that in the past he had not sufficiently appreciated the value of the gradual correction of deformity, in flexed hips and knees he now felt inclined to proceed by splinting rather than by operation.

Mr HARRY PLATT also endorsed the conservative attitude of the opener towards contracted muscles in the correction of deformities, especially of the hip and knee. Mr Dunn had the advantage of working in the Shropshire Orthopaedic Hospital, where the gradual unfolding of the flexed hip and knee had been a conspicuous part of the technique. The speaker had been converted to that method through having as a colleague in one of his hospitals a man who was of that school. He now believed that operations for even the most extreme deformities were absolutely unnecessary, particularly in view of the possibility that later on some form of tendon transplantation in the region of the hip might add just a little—or sometimes quite a great deal—to the gait. The subject of tendon or muscle transplantation was a fascinating one, and illustrated the fashion in operations, from the methods of Volkmann to the simpler varieties of to-day. General principles had been lost in the maelstrom of technique, but there were certain technical principles which were fundamental, and in this connexion the work of Besalaki and Mayer of New York, combining the so-called physiological method of transplantation, deserved much greater consideration than it had received in this country.

Mr G. R. GIRDLESTONE said that his own feeling with regard to one point in the treatment of infantile paralysis was that there had been too much tendency to put the foot at right angles. Most of these patients had two complications, a short leg and a weak or paralysed quadriceps. A rather tight tendo achillis was an advantage, especially from the point of view of dealing with a weak quadriceps. He was greatly in favour of a tight tendo achillis in infantile paralysis.

Mr H. A. T. FAIRBANK was ready to admit that in the past he had operated quite unnecessarily in flexion of the hip, but he had found it necessary to use extension of the hip at night for a prolonged period in order to be quite certain that the patient did not get flexion again, personally he had used a double inclined bed on which the patient slept. The selection of the suitable tendon for transplantation was of first importance, in the foot a flexor would not become an extensor, nor vice versa. The judicious combination of arthrodesis and tendon transplantation made for a good and efficient foot.

Mr ROWLEY BRISTOW defended the case for quick correction of the deformity as against the gradual correction which the opener had supported. Mr Dunn, working at the Shropshire Orthopaedic Hospital, with a team admirably capable of performing this treatment, had advantages which were not available for the ordinary orthopaedic surgeon in London hospitals.

Mr WHITCHURCH HOWELL said that a number of failures in treatment might be traced to the delay in applying stimulation to the transplantations. He now stimulated the transplanted muscle at about the fourth day after operation, with much better results than formerly, when a considerable period was allowed to elapse.

Reviews.

MEDICAL DIAGNOSIS

Books on medical diagnosis are often rather dull reading, as they contain a large number of detailed tests which of course are useful for reference, but this need not be so. In their *Essentials of Medical Diagnosis*,¹ Sir THOMAS HORDER and Dr A. E. GOW, teachers of experience in the great medical school of St Bartholomew's, have placed themselves in the position of a student entering the wards for the first time, and thus have succeeded in expressing their instruction in clear language without any verbal superfluity—in fact, after the manner of Samuel Gee, whose pupil the senior of the authors was. They recognize that the medical student after his first three years, however much he may know about the anatomy and histology of the human body, really knows much less than the art student of three months' standing about the healthy living man, accordingly they have written in an elementary fashion and have clearly set out the mental processes involved in arriving at a diagnosis.

Stress is rightly laid upon the importance of the patient's medical history, and hints are given on how to obtain it and what to omit. The student should, of course, be familiar with the normal, and should closely observe the variations due to surroundings, occupation, and social status, thus the pallor natural to the city clerk would be pathological in the agricultural labourer. The various systems of the body are methodically considered, each one being introduced by a short anatomical and physiological summary. The section on the nervous system has wisely been provided with some thirty pages of these important preliminary considerations and with a number of coloured and plain illustrations. The instructions in the differential diagnosis of the conditions coming under the head of the epilepsies are particularly good. In the next section that on the cardiovascular system, the account of the electrocardiograph is appealingly clear, here as elsewhere the text conveys much shrewd advice and many useful hints.

That this well written and thoroughly practical handbook deserves success there can be no doubt.

CHEMICAL ANALYSIS OF BLOOD AND URINE

THE textbook for laboratory workers bearing the title *Blood and Urine Chemistry*,² in the joint authorship of Dr R. B. H. and Miss I. A. GRADWOHL, is probably the most comprehensive book of its kind. Those who are concerned in giving instruction in modern methods of chemical analysis of clinical material will appreciate the difficulties in compiling such a work as this. It is true that the chemical technique which has to be described is relatively simple. No great refinement of manipulation is necessary to the harvesting of reliable data. Indeed, the methods in general use are remarkable for the ingenuity which has been exercised in rendering them simple, rapid, and well-nigh foolproof. To this achievement the general exploitation of the possibilities of the colorimeter has contributed in high degree, and it is therefore appropriate that the authors should preface their book with a description of the principles and practice of this instrument. On the other hand, the advantages of colorimetry and of simplified technique have led to corresponding complications in the chemical processes exploited. Many methods depend upon the subtle combination of reactions and theories which the medical practitioner may not comprehend without much study.

The difficulty that faces those charged with the exposition of these methods is to decide how much understanding of the principles involved is necessary to the efficient practice of the methods. The authors have met the difficulty by

¹ *The Essentials of Medical Diagnosis*. By Sir Thomas Horder Bt K.C.V.O. MD FRCP Lond and A. E. Gow MD FRCP Lond (London: Cassell and Co. Ltd. 1928. (Cr. 8vo pp xx + 682 19 plates 22 figures 16s net).)

² *Blood and Urine Chemistry*. By R. B. H. Gradwohl MD and I. A. E. Gradwohl A.B. (London: H. Kimpton 1928. (7x10½ pp 542 117 figures 42s. net).)

giving descriptions of the composition and criteria of the reagents employed, the manipulations necessary and the calculation of the results, in such great detail that the analyses can be carried through without any proper appreciation of the intrinsic chemical processes which are being observed. At the same time (in parentheses, as it were, for the more inquisitive reader) explanation is given of the principles upon which each method is based. This description by rule of thumb will be tedious to some readers, but it probably represents a method which is as economical of space as any other for the purpose in hand. The ground covered is very wide. Methods—of greater or less reliability—are given for the determination of all the constituents of the blood whose changes are known or suspected of being of diagnostic value. The section on the analysis of urine is less elaborate. The authors are persuaded that in the blood is written a story of the physiology of the animal which is much more complete and trustworthy than that which can be read in the chemical description of the urine. The third section is devoted to the clinical interpretation of the analytical findings, while the fourth presents a description of the methods available for the determination of basal metabolism—perhaps an unnecessary, but still an interesting, supplement to the book. The chapters on the interpretation of the chemical composition of the blood convey the impression that they are both critical and authoritative. Attention is directed particularly to hypoglycaemia, acidosis, nephritis, and gout. An interesting plea is made for the recognition of the value of blood analysis in surgical as well as in medical practice—for the estimation of operative risk.

As some explanation of the high price asked for this book, it may be stated that it is elaborately produced and profusely illustrated. Many of the illustrations are very helpful, but some of the photographs are superfluous.

DIABETES IN CHILDREN

THIS admirable survey of diabetes mellitus in children,* by KARIN WIDNÄS, is the outcome of observations made at the paediatric clinic in the University of Helsingfors since the beginning of 1924. The author remarks in her introduction that the increase in the number of child diabetes is almost entirely due to insulin treatment, and to the prolongation of life in a malady which previously proved so rapidly fatal in the young.

The value of Dr Widnäs's work lies in the large number of cases she has had under observation, and in the thorough way in which they have been investigated. Her experiences do not differ from those of other observers, but she has a particularly valuable section on the effects of intercurrent maladies on diabetes in children, including the eruptive fevers, mumps, tonsillitis, bronchitis, nephritis, and some local infections. An epidemic of mumps brought five diabetic children under notice. The author observes that mumps may cause a definite decrease in carbohydrate tolerance in children previously diabetic, or may cause diabetes to start as a late complication. She notices that the fasting blood sugar level is easily raised in intestinal infections and certain fevers, also that in diabetic children the fasting level is variable (0.027 to 1.40 per cent.). Like other observers, she finds that acetonaemia and acetonaemia are more readily produced in children than in adults. Dr Widnäs tested the effects of various foodstuffs on children, the chief result was to demonstrate that fats scarcely affect the blood sugar, but that acetonaemia is easily provoked by them in healthy no less than in diabetic children. But she confirmed the observations of Petren and Odén to the effect that very large amounts of fat can be given to diabetic adults and children without producing acetonaemia, provided that a sufficient calorie total is given. She says that the larger the total of calories, independent of their source, the less the acetonaemia, and further, that the total amount of calories plays a more important part than the proportion between ketogenic and anti-ketogenic substances.

This is a challenging and arresting piece of work, which, while it throws new light on old problems, proves that there he beyond still further problems in carbohydrate metabolism.

NASAL NEUROSES

PROFESSOR GREENFIELD SLUDER's monograph on *Nasal Neurology, Headaches, and Eye Disorders** is a large volume containing 428 pages and 167 illustrations. In it has been incorporated much neurological material that appeared in his monograph published in 1918, *Concerning Some Headaches and Eye Disorders of Nasal Origin*. The title has been changed and the present one chosen with the special intention that it may attract the interest of neurologists, internists, and ophthalmologists to a greater extent than the customary treatise on rhinology.

The purpose of the author of this essay is to describe six varieties of nasal disease or clinical pictures having as symptoms headache, more or less eye disorder, and neurological phenomena that are evidently of nasal origin or are controllable by nasal treatment. The six varieties are (1) closure of the frontal sinus without suppuration, (2) anterior ethmoidal (naso-ciliary) neuralgia, (3) the syndrome of nasal ganglion neurosis (lower half headache), (4) the picture of hyperplastic post-ethmoidal-sphenoidal inflammation, (5) some neurological phenomena that are apparently not of nasal origin and are controllable by nasal treatment, and (6) orbital phlegmon.

Hyperplastic disease in the nose and accessory sinuses apparently, in the opinion of the author, is the lesion underlying many of the recurrent headaches and other symptoms making up the clinical pictures. The book is largely taken up with text and figures descriptive of the surgical anatomy and technique of treatment. The opening chapter is appropriately an introduction referring to some points in the minute pathological anatomy of the hyperplastic process. It is written by Dr Jonathan Wright, who says: "It would probably be difficult to find an adult individual in temperate or cold climates who does not present an example of this bone change within his nasal chambers, which we have a right to call pathological. It is only exceptionally that the symptoms to which it gives rise are sufficient to cause him to seek relief." It follows that the practice of the surgical technique described has its limitations.

A chapter descriptive of the author's technique of opening the antrum of Highmore, although hitherto unpublished, is not relevant, and might have been jettisoned to lighten the monograph and to reduce the price of the book. Professor Sluder regards the nose as "an anatomical and clinical region that has special features to be considered (that are self-evident as soon as thought is directed to them) which have not been emphasized even in this day of highly specialized specialties", and, so far as he is aware, no rhinologist has emphasized the neurological side of rhinology. But at the Annual Meeting of the British Medical Association at Bradford in 1924 the late Dr Neil Macleay contributed to the Section of Laryngology and Otology a paper on nasal neuroses, which was, and still is, a most concise and lucid statement of the present-day knowledge of the subject. The first conclusion arrived at by Dr Macleay was that the nasal neuroses were real clinical entities, and he related how pain in the mastoid tip from this source had led to an operation upon the normal bone.

ANTHELMINTIC MEDICATION

ONE of the oldest, and at the same time one of the most distinctive, branches of therapeutics is that concerned with the expulsion of parasitic worms from their host. The study of this subject has in comparatively recent years passed from the stage of uncritical empiricism to that of critical experimentation, and it is remarkable that no book dealing exclusively with this branch of pharmacology and therapeutics has been published. Textbooks on general

* *Études sur le Diabète Sucré chez l'Enfant*. Par Karin Widnäs. Acta Paediatrica vol. VIII Supplementum I. Uppsala. Almqvist and Wiksell. 1928. (Roy. 8vo pp. 208. 45 figures.)

* *Nasal Neurology, Headaches, and Eye Disorders*. By Greenfield Sluder. M.D. F.A.C.S. London: H. Kimpton. 1927. (Sup. roy. 8vo pp. 428. 167 figures. 2 plates. 50s. net.)

* *British Medical Journal* November 26th 1924 pp. 896-898.

therapeutics and on general parasitology alike treat anthelmintics in the briefest possible manner, and, indeed, are often surprisingly inaccurate. It is to meet this need that the work by Major CHOPRA and Dr CHANDLER⁶ has been written. Its scope is ambitious. Beginning with a general chapter on anthelmintics, their choice, method of use, and so on, the authors proceed to a discussion of the helminthic parasites of man and his animals, this discussion ends with a key to the adult larvae and ova. The introductory section also discusses the theoretical correlation between chemical composition and anthelmintic action. The remainder of the book provides a survey of the available information regarding the various drugs which have been used at one time or another, or which may be used in the future, for the expulsion of worms.

While we are wholly in sympathy with the authors' objects, we feel that the volume does not entirely meet present-day needs. A considerable amount of the information is purely theoretical, and many of the drugs discussed are of no practical utility. Moreover, the whole volume displays symptoms of insufficient digestion of the papers listed in the excellent bibliography, and there are several contradictions. The helminthological part is scrappy—many important parasites are neglected and unimportant forms included—and we feel that it is undesirable to embody in a single key all the parasites of man and his animals, separate keys for each species of host would be more effective. Nevertheless, with all its faults, the volume is an effort in the right direction. If it comes to be rewritten—as we hope it may—it would probably be improved by reducing the theoretical pharmacological sections and increasing the more practical helminthological and therapeutical aspects. As at present designed it is a useful book of reference for the library shelf.

MINUTE ANATOMY OF THE CORTEX

IN *Architecture Cellulaire Normale de l'Écorce Cérébrale*,⁷ Dr van BENOUM gives us the material supplied by his lectures to students since 1923. We are accustomed to regarding van BENOUM as a master, and in this presentation of the minute anatomy of the cerebral cortex we are not disappointed. Indeed, it will enhance an already brilliant reputation. The first chapter is devoted to a brief historical summary and to general considerations of the cell-layers and the division of the cortex into isocortex and allocortex. The second chapter deals with the frontal lobe and its chief areas, the third with the detailed variations in cell-structure in the frontal lobe. The next describes the parietal lobe and its fields, the fifth chapter, the insula. In the sixth and seventh chapters the various areas of the occipital and temporal lobes are described. The last chapter, devoted to the limbic lobe, is perhaps the best and most interesting chapter in the book. The material is well arranged and the illustrations are excellent. The use of the same magnification for most of the photomicrographs of the cortex is a very pleasing feature, enabling the student to compare easily the differences in structure of the various areas. There is an excellent bibliography of 64 titles. A translation into English would be very welcome.

NOTES ON BOOKS

THAT a third edition of Professor LOVATT EVANS'S *Recent Advances in Physiology*⁸ should be required within three years of its first appearance is sufficient proof of the well deserved popularity of this work. The present edition has been revised, and two entirely new chapters—the first on excitability and chronaxie, the second on the nerve impulse, subjects of great interest and considerable complexity—have taken the place of two chapters in the second edition.

⁶ *Anthelmintics and Their Uses in Medical and Veterinary Practice*. By R. V. Chopra, M.D. Cantab. Major, I.M.S. and Asa C. Chandler, M.Sc. Ph.D. Professor of Biology, Rice Institute, Houston, Texas. London: Baillière Tindall and Cox, 1928. (Med. 8vo pp. xii + 231. 65 figures, 5 plates. 22. 6d net.)

⁷ *Architecture Cellulaire Normale de l'Écorce Cérébrale*. Par Dr Cor-tantijn van BENOUM. Édition française par le Dr Ludo van Bogaert. Paris: Masson et Cie, 1927. (Imp. 8vo, pp. 183. 61 figures, 80 fr sans majoration.)

⁸ *Recent Advances in Physiology*. By C. Lovatt Evans, D.Sc. Lond., F.R.S. Third edition. London: J. and A. Churchill, 1928. (6s. x 81 pp. xiii + 403. 86 figures. 12s. 6d.)

The second edition of *An Introduction to Practical Bacteriology*,⁹ by Professor T. J. MACKIE and Dr J. E. McCARTNEY, follows three years after the first appearance of this useful guide to laboratory work. In size and shape the present book resembles its forerunner, but a comparison of contents shows that many sections have been rearranged and some new matter added. Thus, brief accounts of the more important pathogenic bacteria of domestic animals are now added in small type, being grouped with other organisms to which they are related biologically. The new classification and nomenclature advocated by the Society of American Bacteriologists is outlined in the first chapter, but in subsequent chapters the older system of designation is retained. In size, shape and contents this is a useful book for students and as a guide to routine tests in the laboratory.

Dr LEVEN'S book *Obésité et Amaigrissement*¹⁰ is an interesting little work because of the originality of his views on the origin of these two conditions. Dr Leven thinks that there is a weight centre in the nervous system which maintains in the healthy a proper physiological weight. When this centre is disturbed by solar plexus irritation from disorders of the digestion, the subject of the disturbance becomes a victim to obesity or the reverse. In this way Dr Leven explains the fact that some fat people remain fat however little they eat, and however satisfactory physically, morally, and sexually their existence may be. Overfeeding, he says, and lack of exercise do not cause fat in a healthy man. The only effect of dieting systems on the obese is that the reduction of food favours an amelioration of his dyspepsia. Holding these views, Dr Leven has no hesitation in thinning the tuberculous or the diabetic when obese. He disputes the definition of indigestible food given in Littlé's dictionary as that which is not absorbed, and substitutes the statement that indigestible food is that which can only be assimilated after an excess of muscular and glandular exertion by the alimentary tube and glands. Perhaps Dr Leven's theories explain why it is so much more easy to make a fat person thin than a thin person fat.

The sixth edition of the textbook of surgery¹¹ by Professor C. GARRÉ of Bonn and Professor A. BORCHARD of Berlin represents a brave and painstaking attempt to include all surgery in one volume of 752 pages, but it shows that we have reached a time when it is impossible to do this successfully. Nothing less than a system of many volumes can now be adequate for the purpose. In a book of such dimensions a certain number of subjects must either be left out or inadequately treated. For instance, we find the operation of supra-pubic prostatectomy dealt with in barely three lines. But this is an extreme case: the parts of the book dealing with abdominal conditions are naturally full, at the expense of other less popular subjects. In short, while this is a useful handbook for clinical practitioners and students, it is not in itself a complete guide to modern surgery.

Radiologie du Cœur et des Vaisseaux de la Base,¹² by Dr H. Vaquez and Dr E. BORDET has now reached its fourth edition. We had occasion in 1920 to report most favourably on the first edition of this monograph, and to recommend it to radiologists and those interested in heart work as being a valuable contribution to the interpretation of x-ray findings as regards the heart and aorta, etc. The authors are well known for their work on the subject, and have added very considerably to our knowledge of what is a difficult branch of radiographic work. This fourth edition has been entirely revised, and a large amount of new material has been incorporated, it is now a book of 500 pages, with 457 illustrations. As regards the latter, very few are reproductions of actual radiographs, they are mostly line or block drawings, many of them made from screen tracings. With all the additions and alterations the authors have maintained and preserved the main features of previous editions, and the very practical character of the book is evident throughout.

This small book¹³ by Dr F. LÓPEZ DUEÑA of Madrid, with a lengthy preface by Dr A. LÓPEZ DUEÑA, treats concisely of the various diseases of the vertebral column and their treatment. It is well printed and clearly illustrated, and should be useful to Spanish speaking practitioners and students but does not call for translation into English. It lacks an index.

⁹ *An Introduction to Practical Bacteriology*. By T. J. Mackie, M.D., D.P.H. and J. E. McCartney, M.D., D.Sc. Second edition. Edinburgh: E. and S. Livingstone, 1928. (Cr. 8vo pp. xiv + 330. Illustrated. 10s. 6d. net.)

¹⁰ *Obésité et Amaigrissement*. Par Dr Gabriel Leven. Paris: J. B. Baillière et Fils. (Cr. 8vo pp. xii + 281. 15 fr.)

¹¹ *Lehrbuch der Chirurgie*. Von Prof. Dr C. Garré und Prof. Dr A. Borchard. Sechste, neu bearbeitete Auflage. Leipzig: F. C. W. Vogel, 1928. (62 x 92 pp. xiii + 752. 500 figures. 31.25.)

¹² *Radiologie du Cœur et des Vaisseaux de la Base*. Par H. Vaquez et E. Bordet. Quatrième édition entièrement refondue. Paris: J. B. Baillière et Fils, 1928. (Cinq. 8vo pp. 497. 457 figures. 60 fr.)

¹³ *Enfermedades del Raquídeo*. Por F. López Dueña. Prologo del Dr. A. López Dueña. Madrid: Javier Morata, 1928. (64 x 91, pp. xxx + 173. 102 figures. Ptas. 12.)

British Medical Journal.

SATURDAY, OCTOBER 6TH, 1928

X-RAY DIAGNOSIS

AT page 595 this week we print the text of a paper by Mr H J Paterson entitled "The fallacy of x rays in abdominal diagnosis," and at page 598 another paper, under the same heading and read on the same occasion, by Dr F Herniman-Johnson. A report of the joint discussion on these two papers by the Sections of Surgery and of Radiology and Physiotherapeutics at the Cardiff Annual Meeting appeared in our issue of August 11th (p 249). We venture to express the opinion, after carefully reading all the communications, that a wrong name has been used to describe the happenings with which they deal. Fallacies in x ray diagnosis there may be, but it seems to us that almost all the 'fallacies' enumerated and discussed at Cardiff would be more correctly described as 'mistakes'.

There is, however, one real fallacy connected with x ray work which has grown with the development of radiology, and to a large degree exercises a crippling influence even to-day. Its consequences have been disastrous and far reaching. It has existed since the beginning, when radiology was looked upon as an interesting toy of the medical profession when sapient physicians and surgeons impressed upon hospital committees that, of course, the hospital must have some sort of quarters for an x ray apparatus, but that, equally of course anyone—medical, pharmaceutical or otherwise—was good enough to run the show as long as he did not spend too much money and was also duly impressed with the diagnostic acumen of his colleagues. This is the false idea which even now survives. No hospital, of whatever kind or size is regarded as complete unless it possesses an x ray plant of sorts and an x ray department. Money can always be found for these. Then the question, the quite secondary question arises as to who shall take charge of the department and be responsible for its work. In the old days any enthusiast who offered his services was promptly accepted, even now in far too many places the hospital authorities consider that any medical man—or perhaps a layman—is fully qualified without any special knowledge and without any special training to be put in charge of the radiological department. As evidence of this, not so very long ago a public body advertised for a radiologist for a hospital "D.M.R.E. preferred" although more than one applicant possessed this diploma another candidate without it was appointed.

The fallacy—a serious one—is therefore, that special knowledge is not required to qualify for the very responsible post of officer in charge of a hospital x ray department. We have it on high authority that at the present time in many of the smaller hospitals of this country (and even in some of the large teaching hospitals too), a vast amount of radiographic work is being done which is so unsatisfactory, both technically and from the point of view of diagnosis that it is a definite danger to the community. Technique is the first essential for accurate x ray work. Without it the finest radiological diagnostician must make numerous mistakes, with it his mistakes will be lessened in number, for none of us is infallible, and no

method of diagnosis is free from risk of error. The other point, so often overlooked, is that even with the finest technique a man's opinion is apt to prove unreliable unless he has a very comprehensive knowledge of diseases and of the pathological conditions which can give rise to the various findings seen on a screen or recorded on films. The fact that it is possible nowadays to get such magnificent radiographs has made interpretation even more difficult than in the early years of radiology. Much slighter deviations from the normal are relied on as evidence of disease, and more remote regions of the body have been explored. Perhaps the greatest difficulty at the present time is to find specially-qualified medical men or women for all these hospital posts. In many districts there is not enough work in private practice to maintain a radiological specialist. A remedy that has been suggested is that in some places a whole time well paid expert might be appointed to take charge of the x ray departments of several neighbouring hospitals.

Besides the papers to which we have already referred, two others on x ray diagnosis appear in this issue. One of these, by Dr Ffrangcon Roberts on chest radiography, is of great interest in showing how mistakes may be made on chest films owing to distortion of shadows. His plea for long distance radiography in the examination of the thorax seems to be well founded. The other paper, by Dr Hubert Williams and Mr Thurstan Holland, is a striking example of a difficulty in accurate diagnosis which occurs in renal stone work. Mistakes there will be, a few of them quite unavoidable even when the most scrupulous care is used and when every possible means of making a correct diagnosis is taken, the radiogram does not lie but interpretation must in some cases be a matter of opinion, and then a wrong diagnosis may follow. Apart from this, the chief of all sources of error is reliance upon technically poor films and an incomplete examination. Other preventable mistakes are for the most part due to want of knowledge.

We cannot agree with those who say that there is no such thing as an x ray diagnosis. A mere glance on the screen sometimes suffices, while over and over again in practically all the conditions for which an x ray examination is made the films alone show, beyond dispute what the pathological condition is. Probably, indeed, no other special method of examination will by itself yield so many positive diagnoses as will the x ray method. This, however, is not said with a view to urging that purely x ray diagnosis should be the rule and we cordially agree that consultation between the practitioner in charge of the case and the radiologist is of the utmost value. If this were always possible many mistakes would not be made. Unfortunately, however, this ideal state of affairs is almost unattainable especially in large hospitals. It is difficult enough for the part time and honorary radiologist to keep continuous control over the routine work, he cannot spare the time to attend consultations or operations. The consulting physician or surgeon is no better off, and he finds it impossible to visit the x ray department as a routine. Individual cases, especially those of much unusual interest may lead to a consultation, but the more ordinary everyday work has to take its chance without.

No doubt papers on mistakes—or fallacies, if that term is preferred—serve a useful purpose, inasmuch as they show how many of these occurrences are preventable but such papers would themselves be a mistake if they were written with the intention to

belittle a method of examination which, in the short space of thirty years, has revolutionized diagnosis and has taught us that many diagnostic points about which it was customary to dogmatize were based on very flimsy grounds. When all is said and done, two things are needed to make a successful practitioner of medicine or surgery—a knowledge of the subject, and, perhaps more important, common sense.

PAIN AND OXYGEN DEFICIENCY

INSUFFICIENT supply of oxygen to the body is a very common result of disease. Although its effects upon the various organs and systems have received the concentrated attention of physiologists, pathologists, and clinicians, little or no attempt has been made to correlate the several aspects of their work. Since oxygen deficiency is so frequent both in health and disease, and since pain is the commonest obtrusive manifestation of perverted bodily function, a relation between oxygen lack and pain might well be predicted, in any case, an inquiry into this matter may serve to link up facts that have been established by the study of particular organs.

Considering first the effects of alterations in the oxygen content of the environment, the account given by Barcroft¹ of the symptoms experienced by members of his party at an altitude of 12,000 feet on the Andes is worth attention. On reaching this height every member complained of severe headache, and in the majority this was the most prominent symptom. If further search is made in this report for the incidence of pain, it is found that four of the party of eight experienced precordial pain, while a fifth had pain in the abdomen. Nor are the less highly developed structures of the body exempt from this same relationship, the severe cramp occurring in untrained muscles with undue exertion, and the painful intermittent claudication arising at times with even slight effort in subjects of arterio sclerosis, are alike the outcome of insufficient oxygen supply. Furthermore, the relationship of cause and effect has been shown experimentally by MacWilliam and Webster,² who shut off the blood supply of the arm by constriction and demonstrated the simultaneous occurrence of pain with active muscular contractions. No organ, however, signalizes the onset of anoxaemia in more dramatic fashion than the heart, and the view that oxygen lack is invariably the fundamental factor in the production of true angina pectoris is ably expounded by Keefer and Resnik³ in their recent study of the pathogenesis of angina. These authors review critically the theory of Allbutt that disease of the aorta is the cause of pain, although aortic disease is usually found at necropsy, it is not invariably present, and, moreover, true angina may arise in adolescent subjects of rheumatic aortic incompetence in whom no involvement of the aortic wall is demonstrable. Against Mackenzie's theory of myocardial exhaustion is raised the cogent objection that in those cases in which insufficiency of the myocardium is most marked—that is, in cases of cardiac failure—angina is a rare symptom, and tends to disappear even if it has originally been present. Indeed, were this the cause of angina all patients dying from failure might be expected to suffer from such pain.

That coronary disease is present in the majority of sufferers from angina is no new observation, and this fact is the principal argument in favour of myocardial

anoxaemia as the causative agent in angina pectoris. The advocates of this theory, however, are confronted with the objection that coronary disease is not invariably discovered, although in its absence aortic incompetence is nearly always present. Since with this lesion the diastolic pressure is usually low, and as the coronary arteries fill during diastole, it is seen that such regurgitation is a potential cause of myocardial oxygen lack. It may further be argued that the preponderance of angina in syphilitic as opposed to rheumatic aortic incompetence supports the anoxaemic theory, since coronary obstruction is more likely to complicate the former than the latter, while a measure of stenosis may partially stem the backflow in rheumatic valvular disease of the aorta, and so aid coronary filling. More light is thrown upon the subject by a study of acute coronary obstruction. In this condition the pain is usually identical with that of angina in character, position, and radiation, the principal difference being the prolongation of the attack. It is known that pain in acute coronary obstruction results initially from permanent interference with the oxygen supply, and it seems reasonable to infer that the brief pain of angina is due to transient oxygen deficiency. Of interest in this connexion are the observations of Herrick,⁴ who has recorded four instances of the association of typical anginal pain with severe anaemia. Since with decrease of the anaemia the seizures of pain also abated in frequency and severity, the conclusion may be drawn that in these cases oxygen deficiency was a contributory factor, if not the sole cause of angina pectoris.

In summarizing the results of clinical and experimental research on oxygen deficiency in the body, it may be remarked that, while all tissues must be affected deleteriously by imperfect oxygenation, it is principally the motile organs and those most constantly functioning which give rise to pain on this account. Far beyond all others in severity and gravity is the pain arising in the heart, for an attack of such pain only too often terminates with complete disorganization of the rhythm of the heart and inevitable death.

OCCUPATIONAL AND PHYSICAL THERAPY

In the years immediately following the war the re-education of the injured received a great deal of attention in this country and in America, and admirable results were achieved. With the closure or reduction in number of the special institutions and departments devoted to this after-treatment much of the ground gained was lost, because it was not fully realized that the physically injured or mentally sick civilian needed this special treatment as urgently as the disabled soldier. Recognizing the existence of this need, the American Medical Association formed a Council (or, as we should call it, a committee) on Physical Therapy, which has recently given its official approval to an important paper⁵ by Dr Harry E. Mock and Mrs Mary L. Abbey. Occupational therapy has been defined as any mental or physical activity which is intended to hasten the recovery of any individual from disease or injury necessitating a long stay in hospital. Dr Mock and Mrs Abbey define three types: (1) diversional, (2) purposeful or curative, and (3) prevocational. Moreover, occupational therapy may be prescribed in the treatment of the neuromuscular system or in the cure of morbid states of mind. As an example of the successful treatment of a purely

³ *Archives of Internal Medicine*, June 1923 p 763.

⁴ *American Heart Journal* 1927 11 p 351.

⁵ *Occupational Therapy* By Harry E. Mock M.D. and Mary L. Abbey. *Chicago Journal of the American Medical Association* September 15th 1923 p 797.

mental condition of hypochondriasis with phobias entirely unconnected with trauma, the history of a case is given by the authors in which congenital occupation of the fingers abolished long-cherished fears of cancer and other diseases. The chief field of operation for occupational therapy is, however, afforded by cases of injury the treatment of which involves protracted residence in an institution and probably immobilization, and by those cases, so familiar in military orthopaedic hospitals, in which damaged and long-rested muscles and joints have to be re-developed, or new actions have to be made familiar to undamaged muscles or groups of muscles. In the United States the movement to forward occupational therapy has gone far and has produced striking developments. The National Association of Occupational Therapists, which was founded in 1917, has 900 members, 7 per cent of whom are "physicians" (It may be necessary to remind the British reader that in the United States "physician" is used generally as an equivalent to "qualified medical practitioner," and does not exclude those practising surgery.) In addition to the association, or connected with it, are twenty local or State societies and seventeen training schools, so that it will be seen that the organization of this form of treatment is well advanced. It is difficult, however, to estimate the extent to which the activities thus outlined are covered in this country by the Chartered Society of Massage and Medical Gymnastics, and the various schools of massage and physiotherapy. Diversional therapy implies anything, in the way of occupation or amusement that will divert a patient's mind from his illness. It may therefore include a game of bridge, the perusal of a detective novel or the solution of a jig-saw puzzle. Drawing is specially advised by Dr. Mock and Mrs. Abbey, since it is not only an amusement, but leads on to vocational work. Above all occupation in the hospital workshop is strongly recommended because of the complete change of environment, the practical value of the work done in muscle training and rehabilitation, and the importance of fitting artisans to resume their old or commence new callings. For tuberculous patients occupational therapy is very valuable, on account of its moral more than its physical effects. In conclusion it is held that there is a strong case for the recommendation that occupational therapy should be employed as a matter of course in every hospital and convalescent home as a part of the course of treatment often as important as that which finds its place in the operation theatre or in a surgical or medical ward.

THE RISKS OF MERCURIAL POISONING

THE danger of chronic mercurial poisoning in certain industrial processes is notorious, but the possibility of mild degrees of poisoning occurring in laboratory work is not so well known. Some recent articles by Stock¹ indicate that this is a real danger. Fleischmann² concluded that a daily intake of mercury of less than 10 μ ($\mu=0.001$ mg.) was sufficient to produce definite toxic symptoms. It must be mentioned, however, that this conclusion has been denied by other workers, and that Fulmer³ concluded that ten times the amount mentioned was required to produce any injurious effect. Stock refers to the notoriously bad effects on health produced by poorly ventilated laboratories. He points out that in an old laboratory the dust is usually full of the mercury that has been spilt from time to time. He suggests that the ill health suffered by many of the most illustrious physicists and chemists was due to mild mercurial poisoning. The symptoms he attributes to mild mercurialism are first, such symptoms of general ill health as lack of energy, headaches, and loss of appetite, secondly, more specific effects associated with the nasal and oral

mucosa, such as sore gums, decay of teeth, liability to nasal catarrh and sore throats, and gastro-intestinal disorders. He quotes the case of one person who suffered from working in a room containing mercurialized dust, symptoms commenced after about six months, and were aggravated in the succeeding six months, but ceased as soon as the room was cleansed thoroughly. Mercury in laboratory dust constitutes a danger to only a very limited class, but mercury amalgam as used in dentistry is a possible danger to a large section of the community. Fleischmann and Borinski showed that there was an undoubted risk to dentists and dental mechanics, for the air in school dental clinics contained quantities of mercury, which reached in one case the surprising figure of 0.3 mg. per cubic metre. Fleischmann detected a definite lymphocytosis in 80 per cent of the attendants, and in many cases found definite symptoms of mercurial poisoning. The possibility of a person absorbing from amalgam dental fillings quantities of mercury sufficient to produce deleterious effects is, however, a much more important question, because such a risk affects a large proportion of the community. Fleischmann found demonstrable quantities of mercury in the urine of patients with amalgam fillings, it appears to be generally admitted that traces of mercury can be absorbed from such fillings. The question of practical importance is whether these minute quantities of mercury affect the health of many out of the millions of persons who have amalgam fillings in their teeth. Stock considers that there is evidence that such poisoning does occur, but it is obviously almost impossible to decide with certainty whether rather vague symptoms of mild ill health are correlated with these stoppings. We are doubtful if any case has been made out against dental amalgams, but the danger of spilling mercury about laboratories seems obvious. Chemists and physicists who are constantly working with mercury are usually aware of this risk, but workers in biological laboratories nearly all use mercury in small quantities for one purpose or another, and are apt to forget that it is dangerous for the dust of the rooms in which they spend their days to be impregnated with this metal.

THE FATE OF INFANTS OF TUBERCULOUS MOTHERS

A DANISH physician Dr. H. Heckscher,¹ has followed up the inquiries of Kjer-Petersen and Ostenfeld by investigating the fate of the 400 living infants born of 141 tuberculous mothers in the maternity department A of the Rigshospital in Copenhagen since 1918. The mothers were, in 82 instances, suffering from active pulmonary tuberculosis when admitted to the maternity hospital, while in the remaining 59 cases they had shown definite signs of pulmonary tuberculosis in adult life, but presented no evidence of active disease at the time of confinement. The fate of only 13 mothers and 32 infants could not be ascertained. The survivors among those whose fate was ascertained were examined clinically. Of 75 mothers confined in hospital in the period 1919-26, and showing signs at that time of clinically definite pulmonary tuberculosis, 11 were found to be well, 31 to be still suffering from tuberculosis, 32 to have died of tuberculosis, and 1 of some other cause. Of the 53 mothers who had been confined during the same period, and who had during these confinements suffered from latent or inactive pulmonary disease, none was found subsequently to have died, 48 seemed to be perfectly healthy, and only 5 showed signs of active disease. With regard to the fate of the 204 infants born to the 75 mothers suffering from active pulmonary tuberculosis at the time of confinement, it was found that 102 were healthy, 46 showed signs of tuberculosis, 11 had died of this disease, 38 had died of other diseases, while the fate of

¹ *Ugeskrift for Læger* July 19th 1928.

the remaining 7 was unknown. As for the 164 infants born of the 53 mothers with signs of arrested tuberculosis at the time of confinement, the subsequent investigation showed that 119 remained healthy, 16 showed signs of tuberculosis, 3 had died of tuberculosis, 25 had died of other causes, and the fate of 1 remained unknown. It should be noted that in these two groups there was a very large mortality (63 deaths) from causes other than tuberculosis, as many as 48 of these deaths occurred during the first year of life. Only in 8 of these cases were there records of a necropsy at which signs of tuberculosis had not been found. It is therefore conceivable that such causes of death as broncho pneumonia and bronchitis (21 cases) were misnomers, the real cause of death being, perhaps, tuberculosis. Adding the figures in one class to those in the other, the author finds that only 14, or 3.8 per cent, of the 368 infants born to the 128 mothers suffering from active or inactive tuberculosis died from this disease. Even if to these 14 there be added the deaths which might conceivably have been due to tuberculosis, the death rate from tuberculosis was still not greater than 9 per cent—a rate far below that said by Calmette to apply to infants born in France to tuberculous mothers. It is a pity that the author was unable to ascertain in each case the degree of infection to which these infants were exposed.

NOISE.

Our readers will recall that at the Annual Representative Meeting of the British Medical Association at Cardiff a resolution moved on behalf of the Edinburgh and Leith Division was adopted calling for measures to be taken for the suppression of unnecessary noise in the interests of public health. Although this resolution made no mention of specific noises, its terms plainly indicated that the reference was to aggressive sounds and vibrations produced by traffic in our streets. The matter was discussed in a leading article in our issue of August 25th (p. 346), and the Medico-Political Committee, at its recent meeting, decided to take prompt action in pursuance of the Cardiff resolution. The Ministry of Health has been asked to receive a deputation, and Branches and Divisions of the Association will be urged to stimulate their local authorities to make use of existing powers to deal with the nuisance and to apply for fresh powers where necessary. In the meanwhile, following an assurance given by the Home Secretary in the House of Commons, a conference has been held at the Home Office between the Secretary of State, the Minister of Transport, and the heads of both departments. According to a statement issued on Tuesday by the Home Office, the purpose of this conference was to consider what steps could be taken in order to mitigate the ever-growing nuisance of noise in the streets, not merely in the metropolis, but throughout the country. "The increase in the volume of noise is largely due to the increase of motors, and of the uses to which motors are put, and to the abuse of various types of horns. The powers and duties in this matter are divided between the two Ministers: the Minister of Transport has the power to make regulations, and the Home Secretary is concerned, as the central police authority, with the measures to be taken for their enforcement. In the result, the Ministers have now decided that draft regulations, directed to abating the nuisance of motor traffic noise, should be prepared. Such regulations will be the subject of consultation between the Minister of Transport and the motoring organizations and representatives of public authorities, whose views will be carefully considered. After the regulations have been made the police will be advised by the Home Secretary as to the steps to be taken to ensure their observance, with a view to decreasing the nuisance from which so many people now suffer."

This is a move in the right direction. But, unless we are much mistaken, continuous prods by the public will be needed to keep the authorities awake. Whether fresh legislation is required or not will probably depend a good deal upon the attitude taken up by the motoring organizations. We are glad to learn, therefore, that the Automobile Association has stated in advance its willingness to support any reasonable proposals to reduce noise.

SUPERVISION OF FOODSTUFFS AND DRUGS

Two reports¹ by Government departments dealing with the supervision of foodstuffs and drugs have just been issued—the report of the Government chemist, Sir Robert Robertson, for the year ended March 31st, and a report on the Sale of Food and Drugs Act, containing the relevant extracts from the annual report of the Ministry of Health for 1927-28 and an abstract of the reports of public analysts for 1927. These reports are in large measure complementary, for, while the major part of the work of Sir Robert Robertson's department consists of analyses for the Board of Customs and Excise in connexion with the assessment of duty and "drawback," it has also some responsibility for the examination of foodstuffs as to quality and freedom from adulteration. The total number of samples examined at the various Government laboratories—being the whole or part of the chemical work of some eighteen or twenty departments—was 491,039, an increase of 21,397 on the previous year's total. A considerable amount of imported dairy produce came under scrutiny, and, in addition, many other kinds of food—fruit and vegetables (pulped, canned, and dried), sweetmeats, custard powder, pickles, etc.—were also examined for the presence of preservatives. Seventy samples were reported as contravening the regulations 44 contained benzoic acid, either in excess of the quantities permitted or where its use is forbidden. It was noted that the use of boric acid as a preservative for butter has practically ceased. Examinations of tea in respect of its fitness for consumption also constituted a task of some magnitude, while, in addition to analyses of alcoholic liquors for excise purposes, the department safeguards the interest of the consumers by the examination of samples of beer "as retailed" for evidence of dilution. In certain cases of proceedings under the Food and Drugs Act, samples may be submitted to the Government chemist, 26 such cases arose last year, 19 relating to milk. The report calls attention to the need for exceptional care in the sampling of milk supplied in the modern type of bottle, which lends itself to the formation of a layer of cream, and, by the absence of air space above the milk, renders difficult the mixing of the cream layer with the remainder. In one case the public analyst called for the prosecution found 2.07 per cent of fat in his portion of the sample, while the portion sent to the Government chemist contained 1.50 per cent, and the defendant's portion 6.68 per cent of fat. Numerous examinations of food and medicinal preparations were made for various public departments, and in other directions the laboratories dealt with a bewildering variety of substances and executed many surprising tasks. Spindle oil was examined in connexion with mule-spinner's cancer, radium was recovered from disused girsights, sheep's teeth were received for inquiry regarding the nature of a metallic deposit erroneously believed to be gold, insurance stamps were tested in cases of suspected fraud, sea water was analysed in its bearings upon fishery research work—these are but a few of the varied activities carried on at the laboratories. The Ministry of Health report is a prosaic document of more restricted scope, and, we may add, somewhat highly priced at eighteen-

¹ London: H.M. Stationery Office or through any bookseller 1928
1s. 6d. net each.

peace for twelve pages of print. It states that of the "record" number of 124,264 samples of food and drugs reported upon by public analysts in 1927, 55 per cent were reported as adulterated, compared with percentages of 58 and 65 for 1926 and 1925 respectively. More than half the specimens examined were milk samples, 69 per cent being below standard or adulterated, the corresponding percentages for 1925 and 1926 were 83 and 74 respectively. Of over 10,000 samples of butter only 14 per cent were reported against. Other foodstuffs inspected included cream, margarine, lard, cheese, bread, flour, jam, marmalade, vinegar, spirits, and beer. During the year, 4,981 samples of 120 different varieties of drugs were examined, 283, or 57 per cent, being found to be adulterated or not up to standard, compared with 45 per cent in 1926. The most interesting case, the report states, was that of some cod-liver extract tablets, sold by a well-known firm of druggists and advertised as being rich in vitamins A and D. The analyst was of opinion that vitamin A was present, if at all, in such a negligible amount as to render the tablets practically valueless as a substitute for cod-liver oil, the deficiency of both vitamins was confirmed by biological experiments, and the vendors were convicted and fined £30 and £75 costs.

MENTAL DEFICIENCY IN NEW ZEALAND

SOME time ago a very influential committee, set up by the Government of New Zealand, inquired into the question of mental deficiency in that Dominion. In a leading article (September 12th, 1925, p. 486) we commented on the report of that committee, pointing out, amongst other things, that the opinions expressed therein were more favourable to sterilization of mental defectives than was the case with informed opinion in this country. Following upon that report, the New Zealand Government this year introduced into the House of Representatives a Mental Defectives Bill based upon the committee's recommendations. The actual text of the bill is not available, but from a summary of its main provisions published in the *Times* it seems that in the bill the term "mentally deficient person" was extended to include "one who suffers from mental deficiency associated with or manifested by anti-social conduct, and who requires supervision for his own protection or in the public interest." If the words quoted are the actual definition of persons to be dealt with under the Act, the latter phrase appears pleonastic and the former sufficiently indefinite to give rise to a good deal of dispute in practice. The bill provided for the setting up of an appropriate board for the supervision of mentally defective persons. The board is to compile a register of such persons, and is given power "to investigate the cases of prisoners or accused persons believed to be mentally defective, epileptic and mentally defective children, and children whose mental development is retarded two years or more." The bill further sought to authorize sterilization with the consent of the patient or of the parent or guardians, and under the direction of the board, to provide special institutions for the segregation of registered defectives, to forbid marriage with registered persons without consent of the board, and to prohibit carnal knowledge of, and the supply of intoxicating liquor to, a registered person. The bill met with considerable opposition in the House of Representatives. It was eventually passed last week, but not until the Minister of Health, Mr. J. A. Young, had withdrawn the more drastic or questionable proposals—namely, those relating to sterilization, to the prohibition of marriage with defective persons, and to the authorization to examine children whose mental development is retarded to the extent of two years or more. The Prime Minister, Mr. Coates, stated that he wished the country to have a further opportunity of considering these proposals.

This was certainly wise, for it requires a good deal of evidence yet to establish their value as practically effective measures, and the Act, even without them, is calculated to achieve its main purpose—the proper supervision and control of mentally defective persons.

ERGOSTEROL

INFORMATION concerning the nature and properties of vitamin D is at present of very considerable interest, and there is no dearth of communications dealing with the matter. In the same number of the *Biochemical Journal* there appear two papers—one by Rosenheim and Wobster,¹ which seems to show that ergosterol is (probably) the only precursor of vitamin D occurring in nature, the other by Havard and Hoyle,² recording observations of the serum calcium and blood phosphate in normal adult human beings to whom ergosterol was administered. The last-mentioned paper is of interest because, as the authors point out, a seasonal variation of blood phosphate has been noted in human beings and in animals, which might be due to the greater exposure to ultra-violet light during the summer months. It was found, however, that neither the administration of 8 mg. per diem of irradiated ergosterol for a period of twenty-one days, nor periodic exposure to carbon arc lamps for sixteen days, caused any significant change either in the blood phosphate or the serum calcium. The experiments were, of course, carried out during the winter months. This work seems effectively to dispose of the view that the undoubted seasonal rise in blood phosphates is due to any effect of ultra-violet light, and it therefore leaves an interesting problem for solution.

ROYAL SOCIETY OF MEDICINE

As mentioned on September 15th (p. 504), Sir William Bragg will deliver the sixth Lloyd Roberts Lecture on November 29th, at the house of the Royal Society of Medicine, 1, Wimpole Street. It is now announced that Sir William Bragg has taken for his subject "Faraday's diary," which will be of particular interest as illustrating the life of one of the pioneers of science, the more so since the diary has not yet been published. Some of Faraday's original apparatus, and pages from the diary, will be on view in the library of the society during a reception, which will be held at 8.30 p.m., prior to the lecture at 9.15. Admission will be by ticket, application for which should be addressed to the secretary of the Royal Society of Medicine. It is also announced that the annual dinner of the society will be held on Thursday, November 15th, at 8 p.m., at the May Fair Hotel, Berkeley Street, W.1, when the principal guests of honour will be the Chancellor of the Exchequer and Mr. Rudyard Kipling.

WE have to announce, with great regret, the death of Dr. D. Noel Paton, F.R.S., late Regius Professor of Physiology in the University of Glasgow. We hope to publish an obituary notice in an early issue.

¹ Rosenheim and Webster. *Biochem. Journ.* 22, p. 762.

² Havard and Hoyle. *Biochem. Journ.* 22, p. 715.

THE annual Corporate Communion of the Guild of St. Luke will be held at the Grosvenor Chapel, South Audley Street, W.1, on St. Luke's Day, October 18th, at 8.15 a.m.; it will be followed by breakfast at Lipton's Café, 484, Oxford Street, if sufficient members signify their wish to attend. The annual general chapter will be held on the same day at King's College, Strand, at 5 p.m. The Rev. Canon C. S. Woodward will preach at the annual service in Westminster Abbey, on October 21st, at 6.30 p.m. Further information may be obtained from the Secretary of the Guild, King's College, Strand, W.C.2.

Opening of the Winter Session.

THE ENEMIES OF MAN.

Address to the Middlesex Hospital Medical School,

BY

A E WEBB JOHNSON, CBE, DSO, MB,
FRCS, F.A.C.S.,

Surgeon and Lecturer on Surgery, Middlesex Hospital

LET us cast our minds back to when the human and anthropoid branches of the anthropomorphous stem were growing apart. We can imagine a time when man's primitive ancestors found that their long stretch in the trees had so straightened out their hip-joints and opened up their shoulder girdles that they could at last comfortably assume and maintain an erect attitude on the ground. We can picture a period when these individuals did not venture far beyond the forest borders, for very early in his life on the plains man must have realized how defenceless he was against his enemies. What special gifts had he to enable him to fight his way through life and become Lord of the World? He was the possessor of a pair of hands. These hands, with their wonderful tool-making thumbs, were unique in the animal kingdom, and, with the intellectual equipment to govern them, enabled man to fashion weapons and to become what he has ever since remained, a tool-using animal—a tireless maker of tools, instruments, and machines. As his dangers and needs pressed upon him, man made steady progress through the millions of years in providing himself with weapons—all the time inventing. Everything had to be learnt, and could only be learnt with certainty by experiment, by research, and by trial. That has been the golden rule all through the ages, and when departed from there has been no progress.

Flint implements have been found which, according to some authorities, carry our actual knowledge of man and his weapons back about six million years, and human remains have been found which may date from half a million years ago. But much later on we find traces of men who lived in caves and rock dwellings, and from their paintings on the walls and their burial customs we learn that man had begun to think of other things besides the means of getting food and the visible dangers about him. He was thinking also of the hidden dangers about him—of health and disease, of life and death.

With the development of agriculture man became fixed to the homo and the soil, and began to live in organized communities. In Egypt, where agriculture was first practised, we find there was an early civilization, and in this civilization a definite place in the community was taken by those practising the healing art. The formation of an army of defence had begun.

It is customary to regard the pre-Egyptian era as an age of mysticism and magic. But medical research had really begun. It was on the wrong lines, and man was groping in the dark, but he was seeking for the light. Diseases were ascribed to mysterious malevolent agencies, and therefore treatment naturally began as a magical rite or exorcism. But later this became associated with the use of medicines or drugs, for man in his search for food became acquainted with plants having medicinal qualities. In the process of development the use of drugs continued and improved while the magical part of the treatment was practised less and less. From early papyrus we learn that the Egyptians had largely given up the magical ritual. Medicine and surgery were fairly advanced, and there was considerable knowledge of hygiene and sanitation. The teachings in the books of Moses show what clear conceptions had been reached, and what research and observation there

must have been to enable such sound rules of preventive medicine to be codified and enforced.

After the Egyptian era came the brilliant age of Greek history, when Hippocrates, Aristotle, and Galen, and their followers, working through the centuries, dug deep and made secure for all time the foundations of medicine as a science. In the Hippocratic works there is no word of superstition. The experimental method was established and medical research was carried on along scientific lines. It was the birth-time of anatomy and physiology, and of the close study of disease by careful clinical observation. Another gift of Greek medicine to our time was the code of medical ethics with which the name of Hippocrates will always be associated. Besides being the founder of the science of medicine, Hippocrates was the founder of the medical profession.

Man had now an organized disciplined army to fight his deadliest enemies. The army waited for light and leadership, but instead of light and leadership, a great darkness fell over the land—a darkness which prevailed in Europe throughout the Middle Ages. But Greek medicine was built on the sure foundations of experiment, research, and trial, and could not die. The remains of Greek learning, discovered by the Arabs in the sixth century in the great world conquest under Mohammed, were brought to the West during the twelfth century. It was not until the fifteenth century, however, when Constantinople fell to the Turks and many learned Greeks were driven to the West of Europe, that the revival of learning began. The scientific world had been asleep. There had been blind acceptance of dogma, instead of experiment, research, and trial, for a thousand years and more.

And now what an awakening! The moving finger writes but its writing is so rapid and the letters are so brilliant that we are dazzled by it all. Great astronomical and geographical discoveries changed man's outlook on the world. Our own land was affected most profoundly, for instead of being on the edge of the known world, Britain found herself in the centre of the suddenly expanded globe. The history of Britain's greatness only began in the reign of Elizabeth, and whatever the glories of Britain in other fields since the hour of her greatness struck, her achievements in the world of science provide by no means her least, and perhaps her greatest, claim to fame for the benefits they have conferred on the human race.

The medical army was aroused with the revival of anatomy in the sixteenth century. The reveille was sounded by Vesalius, a Belgian of Scottish extraction on his mother's side. He was the author of modern anatomy, and laid the foundations of modern medicine. All the old teaching of Galen was raked over, the dust of centuries wiped from it, and the dogmatic statements challenged by the only real tests—experiment, research, and trial. The dawn was hailed by Harvey, the greatest name in British medicine, and one of the greatest in the history of Britain and of the world. This great Englishman compelled a return to the experimental method, and from the time of Harvey onwards medicine became more and more closely linked with the sciences.

During the seventeenth and eighteenth and the early part of the nineteenth centuries much detailed fundamental work was done, hard uphill work, but, as the Norwegian proverb says, "You cannot climb a mountain by a level road." In every one of the sciences progress had to be made by experiment, research, and trial, and we are proud to remember that British workers are to be numbered amongst those whose names will live for evermore. To mention only a few, we have Newton, who led science along new lines, Sydenham, at the bedside, rightly called "the English Hippocrates", Boyle in chemistry, Matthew Baillie, nephew of John Hunter, in morbid anatomy, and our own Charles Bell, founder of our medical school, in

physiology. A new spirit was breathed into surgery by the immortal John Hunter, who found it an applied art and left it a science. His watchword was, "Don't think, try the experiment." Jenner, one of humanity's greatest benefactors, introduced vaccination, and in the great public health movement English statesmen and hygienists led the way.

But still man's chief enemy was not in view. The identification of the enemy and the study of the minute structure of the body in health and disease had to wait for the perfecting of the microscope. Harvey's main equipment was a simple lens, and for some time simple lenses of high power continued to be used. Men did what they could with the instruments at their command, and Bichat and his followers described the tissues of the body. But the compound microscope did not become an efficient instrument until 1830, Lister's father being one of the chief contributors to its perfecting. Results soon followed, and in 1839 Schwann demonstrated that the higher animals are all commonwealths of cells, while in 1858 Virchow published his epoch-making book on cellular pathology.

Man, long suspicious, was now more and more certain that there was something minute at work in his undoing, and in 1862 proof was absolutely established. In discovering "the world of the infinitely small," as he called it, Pasteur made a new world for man, and the whole of our life to-day is based on Pasteur's discoveries. The first great result of Pasteur's demonstration of the germ origin of putrefaction was Lister's discovery that the suppuration of wounds was also due to germs, and that infection could be prevented by antiseptic methods. Pasteur's next great achievement was the scientific attenuation of microbes, and from his researches have been evolved all our present methods of conferring artificial immunity by the use of vaccines and antitoxins.

Man had reached the climax in the fight. The leaders had arrived and the general advance was ordered. The full fruits of victory are still to be gathered, but even so far the discoveries of Pasteur and Lister have conferred benefits on humanity so wonderful, so colossal, and so immeasurable, and they have directly and indirectly saved so many millions of lives, that they stand out in letters of flame above all other achievements in the fight to victory. We may, indeed, echo what the American Ambassador said when addressing Lister: "It is not a profession, it is not a nation, it is humanity itself which, with uncovered head, salutes you."

Advances were swift and sure along the paths opened up by Pasteur. It would be impossible on this occasion to give an account of the many victories achieved. The story of the conquest of the tropics alone would keep you enthralled for hours. It is an epic, full of examples of dogged perseverance, skilful tracking of the enemy, and of heroic and dauntless self-sacrifice by the searchers after truth. The result was not only to convict the enemy hosts of disease, but also to prove the blood-guiltiness of the insect hosts which acted as carriers of infection. The incidents and results of this heroic work were achievements of the order of deeds that men write upon stone. It is just as wonderful that the Panama Canal was cut through a belt of malaria and yellow fever as that it divided a continent into two and linked two oceans together.

In his preoccupation with the larger animals and his perpetual fight to control the vegetable kingdom, little did early man think that his real enemies were microscopic animalcules and unicellular vegetable microbes, and that often the angels of death were of the insect world. Primitive man had to equip himself to fight the enemies visible to him. At long last the hands and brain of modern man had fashioned instruments which brought the real enemy into view. The battle was joined, and man, instead of fighting something mysterious, had the hosts of death captive. He could study them as tiny specks on a microscope slide, or hold them engaged in a test-tube—growing at his command, tamed, attenuated, robbed of their virulence, and oftentimes to be put to man's service.

All through the ages a golden truth is blazoned the path of progress is by experiment, research, and trial

Research must be fostered and encouraged. While it is not given to all of us to add to the sum of human knowledge, we can all help research. We can all be seekers after truth, and ready to explore with open minds the paths indicated by others. Too often a new truth has to fight to acceptance against unreasonable opposition, or against some fixed opinion or bias. It is, therefore, often "not the man who first says a thing, but it is he who says it so long, so loudly, and so clearly that he compels men to hear him—it is to him that the credit belongs" (Sidney Smith).

A study of the history of the fight brings out another lesson. The co-operation of the sciences which dates from Harvey's time must be made closer and closer. It is by co-operation that advances can be made most speedily. Medicine is dependent on the fundamental sciences. From day to day we make greater demands on them for diagnosis and treatment. It may yet be that the dread enemy of cancer will be brought to understanding, prevention, and cure by the chemist and the physicist. Already it is known that there is a difference between the chemical requirements of cancer cells and normal cells, already it is known that radium in proper doses has a lethal effect on cancer cells and spares the normal cells. Further work in biochemistry and biophysics may bring us a means of early diagnosis and successful treatment.

Another point is clear from a study of the advances made. All through the ages man has required for his search more and more elaborate tools, instruments, and machines. To provide equipment of the finest order and laboratories of the best is now a costly matter. Here the men at the base, the men of great generous hearts and far-seeing minds, can help, and have helped. In our own medical school we have been blessed with great benefactors. The Joel Chair of Physics, the Chair of Physiology, and the Courtauld Chairs of Anatomy and Biochemistry are endowed, and you see brought to the service of mankind great institutes for scientific research and application—the Barnato-Joel Cancer Research Laboratories, fast becoming, with the development of radiotherapy, an institute of physics, the Bland-Sutton Institute of Pathology, and the Courtauld Institute of Biochemistry. By these institutes the fundamental sciences of chemistry and physics become closely linked with physiological, pathological, and clinical study, and are brought in very fact to the bedside. Much remains to be done, and in no better way can large-hearted benefactors with the necessary vision contribute to the progress of the race and the winning through of the fight against man's enemies than by the gift and support of laboratories for the study of disease, and of hospitals for its treatment.

But we must ensure that the teachings of research are followed. Even the teachings of Pasteur have not been fully applied. It is nearly half a century since Koch discovered the tubercle bacillus, surely it is time it was banished into the wilderness. The fight against man's deadliest enemies is a fight for all. It is not a fight for armies only, but for nations—a true League of Nations task. Preventive medicine is our aim, and it is worth much labour and much sacrifice. The highest aims of preventive medicine can only be achieved by the co-operation of all health services. There must be a co-ordinating head, which, to act with full authority, should be the State. The great hospitals are ready and willing to play their part by providing accommodation for clinics which it may be desirable to establish. It is for public authorities to make full use of the facilities available and to avoid duplication of services. By co-operation, not only will research be stimulated and fostered and all the resources of the great hospitals be at the service of a great cause, but medical education will go hand-in-hand with research and treatment for the benefit of all.

And now I must make an end. Gentlemen, we have a glorious inheritance. To you the torch is thrown, "be yours to hold it high." Besides the inspiration of a great Cause, you have the knowledge that your own countrymen hold a high place among the seekers after truth, and that men of your own hospital and medical school are numbered amongst those whose names will live.

UNIVERSITY COLLEGE HOSPITAL

ADDRESS BY SIR THOMAS BARLOW

At University College Hospital Medical School on October 1st the inaugural address was delivered by Sir Thomas Barlow, Bt The dean, Dr A M H GRAY, who presided, reminded the company that the medical school was entering upon its second century. During its first eighty years it existed as part and parcel of University College, but for the last twenty years it had been under a separate administration, though it continued to be closely connected with the Faculty of Medical Sciences of the College.

Sir THOMAS BARLOW began with some historical reminiscences. In 1828, when medical classes were started at University College, education in medicine and surgery in London was poorly organized. A certain amount of ambulatory instruction was given by physicians in the great hospitals, but it was of a rather perfunctory character. The surgeons were somewhat more active, they welcomed students as beholders of the celerity and dexterity with which they carried through their operations. In those days a great portion of the medical teaching was carried on in private medical schools, the property of surgeons, or occasionally of physicians. Anatomy and physiology were the chief subjects taught, but at some of the schools medicine, surgery, and obstetrics were also taught. One of these schools existed in the University College neighbourhood when the speaker himself was a student. It was attended by idle fellows who had repeatedly failed at their examinations, but who, by a process of cramming, ultimately scraped through. The novels of Smollett and Dickens, and the drawings of Rowlandson, showed what was thought of the medical student of the eighteenth and early nineteenth centuries. The founders of University College were not content until, courageous and enlightened men, they had built the central block of University College Hospital, and here was accomplished the great work of instituting a medical curriculum and providing a liberal education in the science and art of medicine. The new facilities were not established at the demand of the examining bodies, on the contrary, they acted as a stimulus to the examining bodies to widen their requirements.

Sir Thomas Barlow then addressed himself to the freshmen, who, he said, no doubt intended to take the M B and ultimately the M D of the University of London, and to carry in their stride the examinations of the Coupoint Board, whose diploma would give them the qualification to practise. In their first winter session the important subjects would be anatomy and physiology. They must spare no pains to become neat dissectors and experimentalists, they must cultivate the faculty of making repeated correct observation of salient points, gathering in as much detail as possible, and must cultivate also that part of the faculty of memory which was concerned with visualization. A useful power to acquire was that of summoning up at any moment a mental vision of what had been displayed in dissection or done in the way of experiment. Tactile sensibility as well as vision must be cultivated. It was necessary also to learn to record accurately and tersely. The man who could sketch had a great advantage in dissection, but the next best thing was to be able to make a good diagram which would show not only the shape of the structure, but its relations to adjacent parts. A hint might be taken from commercial book-keeping. A large-sized exercise book should be procured, which might be called the day book, and every night there should be entered whatever was remembered of the day's dissections, then, with the aid of the textbook, what had been omitted or needed to be corrected should be set out on the opposite page. This method would vastly improve the memory, facilitate the acquisition of anatomical knowledge, and lessen the drudgery of the work.

As for lectures *versus* textbooks, Sir Thomas Barlow thought the usual combination of the two was the ideal. Demonstrations, especially catechetical demonstrations, must never be neglected. He warned the students against the great danger of slackness. Because some subjects reappeared in the programme for the second or third year, students were apt to suppose that they could make up by

special application afterwards for neglect at the beginning. That was a mistake, early neglect was a handicap through out the whole of studentship. When the hospital stage was reached, the combination of out-patient and ward work under the same chief was of inestimable value. The student should never be afraid to ask for enlightenment from his chief, but should always be careful not to argue with him! Every opportunity of *post-mortem* study should be taken. The student could not begin too soon to make himself skilled in the handling of instruments of special investigation. It was useful to get a clinical clerkship in the children's ward, also to attend demonstrations at the fever hospitals. In general the student should keep to the medical textbook recommended by his professor, though when working up his commentaries he could go further afield and read some of the original memoirs. The out-patient clinic must not be despised. That and the skin clinic presented something very similar to what would be met with in general practice. Following on a resident hospital appointment, a resident post at one of the special hospitals, if time and means allowed, would be very useful.

In some more personal counsel at the close, Sir Thomas Barlow impressed upon students the need for maintaining their own health. Saturday afternoons should be taken for games. Scratch meals should be avoided, as well as the doctor's villainous habit of bolting his food. Smoking should not be indulged in while at work, and if alcohol were taken it should be only the minimum, and only with food. Time should be found for general reading, the Bible first and then Shakespeare, and the great essayists and novelists, not forgetting biographies, especially medical biographies, among which, in his opinion, Godlee's *Lister* was supreme. Good music and drama had their occasional place, good friendships should be cultivated, and the Union should be joined, but the student should keep up his attachment with his home, and tell his people about every part of his work and play. The preparation for the doctor's life was arduous and exacting, but in the acquisition of medical knowledge there was always the comfort of realizing that through such knowledge came the power to save valuable lives and assuage much suffering.

Dr BATTY SHAW and Professor LOVATT EVANS spoke to a vote of thanks.

LONDON (ROYAL FREE HOSPITAL) SCHOOL
OF MEDICINE FOR WOMEN

ADDRESS BY DR ANDREW BALFOUR

At the opening of the session of the London (Royal Free Hospital) School of Medicine for Women on October 1st the dean, Lady BARRITT, C B E, who presided, stated that there was an entry of sixty students, as compared with just over fifty last year. There would have been a larger entry but for certain misleading statements, widely quoted from a monthly review, which gave a quite wrong impression as to the clinical facilities afforded to students at the hospital.

Dr ANDREW BALFOUR, C B, C M G, addressed the company on the possibilities of the tropical field for medical women, saying that it offered abundant opportunities alike to the medical practitioner, the research worker, and the public health administrator. Slowly but surely the mastery was being obtained over tropical maladies which not long ago were considered mysterious in their cause and mode of spread. The habit of viewing tropical diseases was also changing. Until recently there was an imaginary gulf between diseases in temperate climates and diseases in the tropics, but in fact there were only three tropical maladies—in the sense of maladies strictly limited to the belt between Cancer and Capricorn, these were African sleeping sickness, South American human trypanosomiasis, and African tick fever. Many other so-called tropical diseases, even including sprue and yellow fever, were not strictly diseases of the tropics, although, partly owing to their etiology, and partly to environmental circumstances, they prevailed nowadays to a much greater extent in hot countries than elsewhere.

Africa had ceased to be the "dark continent" because it had been enlightened by the doctor and the engineer.

One of the pressing questions now in many parts of Africa was the prevalence of tuberculosis, which appeared to be a graver problem year by year. Everywhere in tropical Africa malaria remained a scourge, and in many places its dreaded sequel, blackwater fever, took its toll of human life. Yellow fever on the West Coast had of late given much cause for anxiety. Sleeping sickness still held sway over vast territories, in spite of modern knowledge of trypanosomes and their vectors. In several parts of British tropical Africa steps were being taken to train medical men and sanitary inspectors, and in some corners of the continent maternity and child welfare work was being actively developed. Africa was moving in the direction which this country had trodden, with increasing security, for the past twenty-five years, and, unless he was very much mistaken, this spelt openings for women.

The medical problems in Palestine were mainly those of northern Africa. Like Egypt, it was a great country for the oculist. Any woman doctor who had specialized in eye work should find an opening in the Holy Land. Iraq was another country where medical women should find a place in the sun, the phrase was an apt one, because it was the sun which determined the pathological and epidemiological characteristics of the country of the Tigris and the Euphrates. The diseases of Iraq were chiefly malaria, plague, cholera, oriental sore, and dysentery. Iraq being a Mohammedan country, the practice of midwifery and gynaecology was backward.

India remained the Mecca for the woman doctor. Hinduism, with its blighting system of caste, exercised a malign influence on women's lives and health. But many conquests had been made. Kala azar, which once doomed its victims readily to death, yielded, as a rule, to antimony, the position in regard to leprosy had improved greatly. Hookworm disease was now under control. Altogether the problem at present was not so much to acquire knowledge as to apply the knowledge gained. Ceylon was a wonderful place for diseases, and not far behind India as a pathological museum. The Federated Malay States, in addition to the customary problems of the East, presented some special questions, which added interest and variety to medical practice. One of the chief diseases was beri-beri, and there was said to be a form of beri-beri occurring in the puerperium.

Much of China was in the tropics, and everywhere there was a great burden of disease. China was a mine of pathological wealth, and it had been a great centre of medical missionary enterprise and a country where many women doctors had found their vocation. The islands of the Pacific, even Fiji and Samoa, in which latter island two women doctors were practising, need hardly be taken seriously in such a purview as this, but, passing to the South American continent, British Guiana was a happy hunting ground for the clinician, and what was true of British Guiana was true, generally speaking, of the West Indies. In all these places there was much to be done, both from the preventive and the curative aspect.

With regard to the scope for medical women, Dr Balfour considered that India offered the greatest opportunity. Here medical women might engage in the Women's Medical Service for India (founded by the Countess of Dufferin's Fund), in the mission hospitals, nearly one hundred of which were staffed by medical women, in private practice, which appeared to promise success only in the larger towns, and, finally, in public health work. Dr Margaret Balfour had written to him stating that it was astonishing that medical women were not more freely employed in India. Not a single medical woman was attached either to the public health department of the Government of India or to the departments of the Provinces. There were 62 hospitals in India staffed by women doctors, apart from the mission hospitals and the Women's Medical Service for India, these were mostly hospitals of the provincial Governments and municipalities. In Africa the most advanced work was being done on the Gold Coast, where there were properly constituted maternity and child welfare centres. In Palestine there were 31 infant welfare centres, and 37 women were licensed to practise midwifery. In Malaya about 16 women medical officers were in Government employment, and the number was likely to increase. In Hong-Kong

there were two medical women in official positions, here private practice could be built up, and would in time become lucrative.

Dr Balfour concluded by urging the need for special preparation for tropical conditions, and for the highest standard of personal fitness and professional efficiency. A vote of thanks was accorded to him on the motion of Professor WINIFRED CULLIS, seconded by Mr JOSEPH CURNING, senior surgeon to the hospital.

WESTMINSTER HOSPITAL

INAUGURAL ADDRESS

THE new session at Westminster Hospital Medical School began on October 1st, Sir WILLIAM GOSCHEN presiding at the opening meeting, when the inaugural address was given by Mr A. C. POWELL, headmaster of Epsom College, who took as his subject "Leisure and the medical student."

Mr Powell said that the world was calling out more insistently than at any time for educated men and women in all the professions, and in medicine the need for all-round culture was, to put it mildly, as urgent as was the need in any other high calling. He feared the supply was not altogether worthy of the demand. In years gone by the country practitioner was as often as not the universal encyclopaedia, the arbiter of taste, confessor, comforter, and general autocrat. Infinitely inferior in technical skill and knowledge to the general practitioner of the present day, he had, nevertheless, valuable qualities that it would be well for men of our generation to cultivate. It might be asked whether there was any longer time available for the medical student to be anything but a medical student. Emphatically Yes. Our days were too kinetic, a little more knowledge of the laws of statics would prove a salutary medicine for the modern disease of "mobilophobia." Lack of control of the time of leisure, however small it might be, was one of the present-day curses. Even in this hectic age some portion of it might be made productive of future good without losing its value as relaxation. Purposeful leisure had been established as one of the fundamentals of civilized life.

Dr A. S. WOODWARD, dean of the Medical School, stated that the financial position was eminently satisfactory. Two classes had been held for captains of the R. A. M. C., and the authorities had asked them to continue these classes. Twenty-eight officers completed their course last week, and a very successful post-graduate class had been conducted for doctors from all over the world. The number of students in the hospital remained unchanged from last year, which implied that the entry had equalled the exit of those students who had become fully qualified. During the last two years some sixty students had taken their degrees and diplomas. Among the prize-winners whose names were announced was Mr R. G. L. Waller, winner of one of the certificates and prizes offered by the British Medical Association. Dr Woodward mentioned that the school had that day attained its ninety-fourth birthday.

ANNUAL DINNER

The annual dinner of the Westminster Hospital Medical School was held at the Royal Adelaide Gallery on October 1st, with Sir James Purves-Stewart in the chair. Replying to the toast of "The School," which was proposed by Lieut-Colonel Bulkley, the dean (Dr A. S. Woodward) said that from every aspect they had good reason to be satisfied with its position. One of the most pleasing features was the growth on the athletic and social side. They were not only doing routine work, but were engaged in research of world-wide importance, publication of the progress made might soon be possible, when its excellence would be revealed. For the last five years they had been conducting pioneer investigations in connexion with radium, and the hospital had been visited by doctors from all over the world to see what was being done. He desired to express his gratitude to Mr Stanford Cado and others for bringing the hospital to the front in this matter. The toast "Past and Present Students" was submitted by the chairman, and replied to by Dr H. H. Mills and Mr

C G Roberts In proposing "The Guests," Mr Arthun Evans referred to the need for providing hospital accommodation for paying patients of the middle and professional classes. They were alive to this question at the Westminster Hospital and had available an excellent site, all they lacked was the capital. He appealed to all old students to think of the hospital and of the need for filling this gap in its life. The matter merited the attention of the leading insurance companies. If the provision of such accommodation meant that the lives of middle class people could be prolonged by three or four years, the additional premiums payable would result in such an accumulation of funds by the companies that the interest alone would more than suffice to furnish the money necessary to carry out the scheme. He suggested to the insurance companies that they would save money by giving it to the hospitals. The headmaster of Epsom College replied, and the toast of "The Chairman" was proposed by Dr Arnold Stott.

ST BARTHOLOMEW'S HOSPITAL

OLD STUDENTS' DINNER

No formal ceremony marked the opening of the new winter session at St Bartholomew's Hospital, and even the annual old students' dinner, which was held on the evening of October 1st, in the Great Hall of the hospital, had the nature of a family reunion.

Sir D'Arcy Power, who took the chair, was supported by Lord Stanmore, treasurer of the hospital, Sir John Rose Bradford, President of the Royal College of Physicians, Surgeon Vice-Admiral Gaskell, Air Vice-Marshal Munro, the Master of the Apothecaries Society, Sir James Berry and the headmaster of St Paul's School, as well as by senior members of the hospital staff. In proposing the toast of "Prosperity to St Bartholomew's Hospital and College" the CHAIRMAN referred to the sad loss sustained during the past year by the deaths of the two senior consulting physicians, Sir William Church and Sir Dyce Duckworth. In regretful mention of the retirement of Mr Douglas Haimer from the charge of the throat department, which he had held for more than a quarter of a century, the hope was expressed that he might now have leisure to conduct some of the very necessary throat investigations. Sir D'Arcy Power referred also to the Harvey celebrations last spring, mentioning particularly the successful lunch held in the Great Hall, when Sir Wilmot Horringham delivered his magnificent address on Harvey's connexion with St Bartholomew's. He recalled attention also to the fact that another member of the hospital, Mr Geoffrey Keynes, had prepared for publication in the month of the tercentenary celebrations the first version in English of *De Motu Cordis* and a Harvey bibliography. Building operations at the hospital had continued during the year, and a fine memorial of the great work of Miss Isla Stewart as matron would soon be available in the form of the recreation room for nurses, which was now nearly complete. Steady progress was being made with the new surgical block, no finality as regards building was possible yet, or was in contemplation. The hospital took pride in the fact that the accommodation provided for the treatment of the sick poor was always a little in advance of that generally considered adequate. Passing to the subject of athletics, Sir D'Arcy referred to the return of the inter-hospital Rugby football cup into the keeping of the medical school for the fourth time, and mentioned that, in the excellent entry of new students, a large number of men were included from Oxford and Cambridge, among whom some had already gained their "blues." Lord Stanmore proposed the health of Sir D'Arcy Power, which was drunk with musical honours.

This was the first occasion on which the new lighting in the Great Hall was brought into use. From the embrasures of the upper windows reflected light was thrown on to the fine old ceiling, and revealed the fact that, after some fifty years, the work of cleaning had now been undertaken. At previous dinners comments were often made on the severe gloom of inadequate lighting, and the adjournment to the library has always been popular as soon as the

dinner came to an end. Whether it was the new lighting or the jovial comradeship of senior and junior members of the staff, or the reviving of old friendships, it was very apparent this time that there was no inclination to leave the hall at an early hour. Eventually, however, the company reassembled in the library, where the flow of reminiscences continued, and the prospects of the future were discussed. It may be mentioned that one of the chief needs of the medical college to-day is a new department of anatomy, a site has been obtained, but the money required for building has yet to be found. Perhaps by way of contrast with these newer performances and projects, the front page of the menu card was adorned with an illustration of the old chemical theatre of 1849.

MOTOR CARS FOR 1929.

THE OLYMPIA SHOW

[FROM OUR MOTORING CORRESPONDENT]

It has become customary to speak of each succeeding annual motor show at Olympia as the best of all, but there can be no doubt that this is true about the 1928 exhibition, which will open at 10 a.m. on Thursday next, October 11th, and continue until Saturday, October 20th. The show will provide the threefold attraction of great variety in the types of cars, new and interesting mechanical features, and cars of each class vying with each other in competitive price to attract the public.

An International Display

The Olympia show has a wider international character than any of the motor exhibitions held in other countries. Indeed, from the advance information so far available it would appear to be likely that Olympia will next week have under its roof at least as many examples of foreign makes of cars as of those of British construction. The United States and France are, of course, the biggest competitors, not only for the British but the world's trade in motor vehicles, but with them Austria, Belgium, Italy, and Canada are also as usual contributing their quota, while several German car-manufacturing concerns will also be represented.

The Car Requirements of Doctors

Just as there are motorists and motorists, so are there doctors and doctors, whose requirements and circumstances vary so considerably that it is impossible to pick out any one type of car as being most suitable for the doctor's use. Whether he lives a town or country doctor or whether his practice is large or small the medical man who visits the show will find a choice of cars to meet his requirements and his means. The range of choice extends all the way from one of the "babies" in the £125 to £150 class, through the popular four cylinder cars between £150 and £250, to the more elaborate vehicles with six or eight-cylinder engines, varying in price from £250 to £600 and over. Whatever class of car is selected, from the point of view of the medical motorist the great desiderata are reliability, comfort, and smart appearance rather than luxury. Good all-weather protection and good lighting—especially for country practitioners—are also extremely desirable features. Further, the doctor's car, particularly when used in towns, has to be started and stopped frequently, so that the engine-starting installation, and especially the capacity of the battery used in connexion with it, is a point that should not be overlooked when considering the respective merits of different vehicles.

1929 Cars Better Value for Money

Except for improvements in detail and the indication of new tendencies, to be alluded to later in the present article, 1929 cars will not be found to embody any startling mechanical developments. The principal changes that are taking place lie more in a general smartening up in the outward appearance and comfort of British cars, matters in which, in the opinion of many users, they had fallen somewhat behind the productions of some American builders. Thus external painting in two or three colours instead of one promises to be one of the features of the show, although whether this will appeal to doctors, who

usually prefer cars with bodies painted in a quiet but agreeable colour, remains to be seen. Makers are also vying with each other in their efforts to cater for the comfort of both the driver and the passengers by including in the specification many little conveniences that were previously regarded as luxuries to be paid for as extras.

As regards the prices of cars there was a rumour early in August that these would, for 1929, show an upward tendency, a rumour which, however, was quickly killed by the announcement of the reduction in the prices of Austin and Wolseley cars. While, therefore, increases are not numerous—there are one or two—the same can also be said of reductions, the general tendency being apparently to maintain the old level of prices, but to include in the specification certain additional fittings. Generally speaking, the opinion may be expressed that while cars are no cheaper they are in reality better value for money than ever.

New Car Fittings and Conveniences

Among the new fittings which promise to form a feature of next year's cars are bumpers, and dipping headlights or lamps fitted with dipping reflectors. The bumper, fitted mostly to the front of cars and often to the rear, is an American idea and a natural outcome of the immense motor traffic in the United States, where instances of cars bumping into each other are quite ordinary events. So far this device has not been widely adopted in this country, where, notwithstanding the great increase of motor traffic, car owners have hesitated to incur the expense of having them fitted. But now that at least two concerns—Morris and Clyno—have adopted them as part of the standard equipment, the example is likely to be followed by other makers.

The Dazzle Problem

As to the second new feature, those drivers who have to do much after-dark driving know that one of the great difficulties is that of dazzling headlights. These, while admittedly a necessity for safe driving along unlighted roads, are a source of great inconvenience, if not of danger, to the drivers of oncoming vehicles, as well as to pedestrians and cyclists. The problem is one that has received considerable attention, but the real solution has not, in the writer's opinion, yet been found. During the past year or two various forms of dipping headlights or headlamps with dipping reflectors have been introduced, and by some car manufacturers these are being standardized for the coming season. If they reduce the risk of accident it will be all to the good, but with many motorists the question of "to dip or not to dip" is still an unsettled problem. Indeed, if the number of cars on the roads continues to increase at the present rate it would seem that either the driver will have a busy time in working the dipping control lever or dipped headlights will have to become permanent.

Among the other general tendencies to which brief reference may be made are the increasing use of unsplintable or safety glass for the windcreens and windows of cars, the use of chromium non-rusting plating for the external metal work—this being now a feature of many American cars, and direction indicators, which are now very widely used in Germany and Holland, and are becoming increasingly popular in this country.

The Approach of the £100 Car

It may be remembered that one of the features of the Olympia show two years ago was the display of two or three attempts to produce a small car at the round figure of £100. Although none of the cars shown in 1926 have survived, each year sees us approaching the attractive round figure in cars actually made by established manufacturers. As is well known, the Austin Company led the way in this direction with its ever-increasingly popular and useful "Seven," the price of which has been reduced to £125 for the touring car and to £135 for the saloon. The field of "babies" is, however, rapidly increasing, for not only is the Triumph Company continuing its "Seven" at a reduced price, but one of the great attractions of the show will be the Morris Minor, introduced by the Morris Company, this little car is being built in open and closed forms at the same prices as the Austins. None of these will, however, be the lowest

priced vehicles in the exhibition. This distinction belongs to Jowett Cars, Ltd., who are offering a saloon at £125. Although fitted with only a two-cylinder engine, the Jowett car has now withstood the test of several years' running, and by reason of its economy and reliability has attracted a host of satisfied users.

Catering for the Owner-Driver

While, of course, there is a wide choice of luxurious cars for the wealthier classes, who regard motors purely as a means of transport and are in a position to employ an expert mechanic-driver to maintain their cars in proper running condition, one of the outstanding features of the 1928 exhibition is the great attention that continues to be paid by manufacturers to the requirements of motor users who not only drive, but also look after their own cars. It is true that during the past year or so there has been considerable progress in car "servicing" facilities, it being now possible to call at many garages and not only have one's car quickly cleaned and polished, but also have tyres pumped up and repaired, and the various parts of the chassis given a charge of lubricating oil or grease. The true owner-driver, however, likes to be able to look after his own car as far as possible, so that he may know when setting out on his journeys that everything is in proper order. It is therefore satisfactory to find that not only is there a wide selection of cars of the owner-driver variety to suit every pocket from about £112 upwards, but that makers are studying his requirements in respect of easy maintenance. One example of this is seen not only in the reduction in the number of points about a chassis that need periodical attention—as, for instance, oilless spring shackle bolts—but also in what is known as "one-shot" greasing, by which all the different parts requiring grease are supplied from one central point.

1929 to be a Six-cylinder Year

It may be interesting to study the modern car as shown by the 1929 models, step by step—that is to say, by regarding each of the principal chassis components in their turn. Naturally one begins with the component which supplies the motive power—the engine. In this the note of the forthcoming show is the ever-increasing vogue of cars with six- and eight-cylinder engines, particularly the former. The car for the man of extremely moderate means continues, and will probably continue for some years, to be provided with a four-cylinder engine. This variety of engine is capable of meeting all ordinary requirements of power development and smooth running, and has, moreover, the advantage of simplicity, together with low cost of running, maintenance, and taxation. The ever-growing motor-using public includes, however, people who are prepared to set aside considerable sums for the acquisition and running of a car. One finds, therefore, an increasing number of cars fitted with six-cylinder engines, indeed, fully 50 per cent of the cars to be exhibited next week will be of this type, some with a price as low as £250. The show will also be notable for the appearance of an increasing number of cars fitted with "straight-eight" engines. So rapidly, indeed, is the trend of design turning in favour of six or more cylinders that there are now several firms in this country and abroad that are confining their productions to six-cylinder vehicles, while there are some which are building only "sixes" and "eights," leaving the production of "fours" to others. There are even those who prophesy that the car with a four-cylinder engine—certainly for anything over 12 h.p.—will be virtually a thing of the past in a year or two, that six-cylinder engines will be practically universal for even popular-priced vehicles, and that the more expensive cars will have engines with eight and twelve cylinders.

Great attention is also being devoted to carburation and to the filtering of the air before it passes into the vapourizing chamber. The modern petrol engine, whatever its number of cylinders, is to-day almost universally provided with a detachable cylinder head to facilitate the decarbonizing of the combustion chambers and piston heads. As for valves, the overhead type is still slightly more common than the rest, but there appears to be a tendency to revert to the valve-at-the-side type of engine for small and medium-power cars, while for the larger vehicles the sleeve-

valve engine is very popular. As regards ignition, American influence is being felt in the use of coil ignition, with current supplied from the dynamo and battery, although magneto ignition (for which the writer has a preference) is still largely used.

Gearbox Changes

Coming now to transmission, our notes that the once almost universally used cone type of clutch is but rarely met with to-day, the disc or single-plate variety being far and away the most popular. As to the number of speeds, although a gearbox with only three speeds is the one most largely used, it is interesting to note that one well-known British maker of popular-priced 10 h.p. cars has decided to fit a four-speed gearbox in future. There is no doubt that in very hilly districts four speeds are a distinct advantage. Even in fairly level areas there must be many motorists who wish they had still another speed at their disposal, especially with four-cylinder cars, which lack the engine flexibility of "sixes" and "eights."

Although in gearboxes the sliding pinion variety continues in universal use—even the modern Ford car being fitted with a change-speed gear of this pattern—foreknowledge of this year's exhibition seems to indicate that designers have at last begun to realize that something better and simpler for the purposes of gear changing is necessary. Thus at the 1928 show there will be several cars fitted with improved forms of change-speed gears, either as standard fittings or as alternatives to the usual pattern that can be supplied at an extra charge. Among the former are the Cadillac cars, which are now fitted with what is known as the "synchromesh" transmission, in which the different gears are always in mesh and brought into action by special dog clutches. The new Graham-Paige car is also notable for an improved four-speed gearbox in which both the third and fourth speeds are claimed to be extremely silent. The Armstrong-Siddeley Company have taken up a new mechanically operated change speed gear, which, although not yet used as standard, can be fitted when required. In the new arrangement the driver has still a pedal and a lever to operate to effect a change of gear, but the ordinary procedure is greatly simplified by means of a gear selection lever located on top of the steering column instead of at the driver's side. The usual type of clutch is dispensed with, the clutch mechanism being incorporated in the gearbox. To change gear the small lever on the steering column is moved to the position on the quadrant indicating the desired higher or lower speed, and the pedal is depressed when the actual change becomes necessary. There is also the Robertson automatic variable speed gear in which a novel centrifugal governor is embodied in the engine flywheel, which causes a driving face to come into contact with a driven member in line with the usual propeller shaft. As the engine speed increases the driven member is moved as a whole in such a way as to provide a ratio suitable to the speed of the car and power development of the engine. A simple reaction arrangement, which permits of what amounts to engaging a lower gear, is provided so that acceleration and hill climbing capacity can be increased at will.

A year ago much interest was aroused in a new departure involving the introduction of a free-wheel device between the gearbox and the final drive to the rear axle. By this means, when the clutch is released, the car can overrun the gearbox, in other words, the gear can only be driven by the engine and not by the rear axle. Although it is claimed that this facilitates easy and quiet gear changing, and has the further advantage of making it possible to coast without declutching, the idea, though still alive and to be seen at the show, does not appear to have met with any widespread adoption.

Better Brakes on Next Year's Cars

For the driving of the back axle, while there are a few makers who still pin their faith to worm or straight bevel gearing, the spiral form of bevel gear is still the most widely used. In the case of chassis springing, despite the many attempts that have been made to use other forms, the semi-elliptic continues the most popular. Shock absorbers are, however, now fitted in practically all types

Increasing attention is being devoted to the brakes of cars, a vital point in view of the steady growth in the number of vehicles on the roads and the increasing risk of accident. Four-wheel brakes are universally fitted, while on the popular-priced vehicles a good point is the adoption of larger diameter brake drums. On the larger cars, as well as on some small ones, there is an increasing tendency to adopt what are known as "servo" brakes, in which the degree of braking effort of the shoes on the drum surfaces is mechanically or pneumatically effected, and is, therefore, not dependent on the pressure on the brake pedal which the driver can apply.

Wheels and Tyres

With regard to wheels, the wire type would appear to be the most popular, the steel-spoked wheel is, however, still largely used. Disc wheels, although easily cleaned by the owner-driver, do not seem to be so greatly favoured as a year or two ago. As to tyres, the low-pressure balloon type is now used on the majority of cars, and their wearing qualities and reliability are such that mileages are being obtained from them which ten years ago would have been regarded as impossible.

Improvements in Car Bodywork

In the bodywork of cars one finds evidence of marked progress. The tendency is more and more towards the use of covered rather than open cars, and as a result of the experience gained, the increasingly popular saloon type shows distinct improvement, of which noticeable features are larger windows and less prominent posts or uprights in the wood or metal work of the bodies, giving the driver and his passengers a less obstructed view than formerly.

Although there is no gainsaying the popularity of covered cars, even their most enthusiastic users admit there are occasions when they and their passengers would prefer an open air drive. It is therefore interesting to note the increasing choice of saloon cars the roofs of some other portion of which can be quickly and easily opened, and which combine, therefore, the advantages of the open and closed type of vehicle.

Fabric Bodies

Another outstanding feature of the 1928 Olympia show will be the rapidly increasing vogue of what are known as fabric bodies—bodies in which a fabric material or leather cloth material is used to fill in the framework instead of metal or light wood panelling. Introduced some years ago in France, the fabric body is claimed to be not only light and more suited to withstand chassis strains, but also more easily cleaned than the usual painted panel bodies. It has made steady progress in popularity during the past season, with the result that cars with fabric bodies will be found on most of the stands.

The exhibition authorities have again adopted the plan of making the opening day of the show—Thursday, next—a special event, the entrance charge, with the object of preventing overcrowding, being 10s. The popular days are the two Fridays and Saturdays, when admission costs only 2s 6d, while on all other days it will be 5s. Finally, it may be mentioned that the exhibition will be open each day, except Sunday, from 10 a.m. to 10 p.m. Next week it is proposed to refer in greater detail to some of the features of the show, and to the cars specially suitable for the use of medical men.

'THE AUTOCAR BUYERS GUIDE

THE current issue of *The Autocar* (dated October 5th) contains the Annual Buyers Guide a feature which is always appreciated in view of the approaching Motor Exhibition at Olympia. This guide is designed to help intending purchasers in their choice of a new car, and comprises alphabetically arranged tables of all 1929 model cars, both British and imported, on the British market, with their full specifications, principal measurements, annual tax, and weight together with the prices of chassis open tourer, and saloon models. The Buyers Guide is full of useful information and in view of the many new and improved cars which will be staged at Olympia, and which will embrace an attractive range of medium-powered six cylinder cars, this feature should prove of great value to motorists and prospective car buyers for purposes of reference and comparison. With the guide is a composite drawing of a chassis based on an analysis of the guide, showing graphically the most popular type of car for 1929.

MEDICAL DEFENCE UNION

ANNUAL GENERAL MEETING

THE annual general meeting of the Medical Defence Union was held at the Norfolk and Norwich Hospital, Norwich, on September 29th, with Sir HERBERT WATERHOUSE, the president, in the chair.

In proposing the adoption of the annual report for the year 1927-28 Sir Herbert Waterhouse said that this was the third occasion on which it had been his privilege to preside at an annual general meeting of the Union, and that each year he had been more and more impressed with the value of the work in which it was engaged, and with the excellent manner in which this was done. During the past year they had had to defend an unusually large number of High Court actions, and in only one of those cases had the verdict been against the member. Of the great variety of cases dealt with each year, fractures of the neck of the femur gave, perhaps, the greatest anxiety. In the last twelve months these cases alone had cost the Union over £1,400. Time after time at council meetings the secretary reported cases in which claims were made against members—in nearly every case due to the fact that the presence of a fracture was overlooked at the time, and only discovered as the result of an x-ray examination made generally months later. Claims were nearly always based on alleged negligence in that an x-ray examination was not advised, and unless it could be proved that such advice was given the defence of a member became a matter of great difficulty or even impossible. Sir Herbert Waterhouse understood the British Medical Association had given as its considered opinion 'That it is not possible to define a group of injuries to bones or joints the diagnosis and treatment of which can be said in advance not to require examination by x-rays, and that whether such an examination is or is not necessary in an individual case can be judged only by the practitioners concerned.' He agreed with that pronouncement, but the practitioner in making his decision should remember the possibility of legal proceedings in the future, and should see that his defence was not prejudiced by the absence of proof that he had taken all necessary precautions. Allegations of negligence undoubtedly constituted the greater proportion of the cases in any year, these cases, as a rule, did not arise until the doctor's account was sent in, and much assistance in rebutting such charges was obtained when the member had kept careful notes of the condition when the patient was first seen and the progress of the case from day to day.

When he became president in 1925, Sir Herbert continued, the membership of the Union was 12,916, it was now 15,474. In that period the available funds had increased from £36,723 to £57,810. In these days of costly litigation the possession of a substantial reserve fund was of the greatest possible importance to a defence society, and the members of the Union had every reason to be gratified with the present position. It had been the intention for some years to build up a substantial reserve fund, so that it would be possible, if necessary, to carry a case to the House of Lords, he thought that in some measure this had been achieved, for the investments now amounted to £35,000.

During the last few years women doctors had joined the Union in increasing numbers. They seemed to be liable to very much the same attacks as those which men doctors were called upon to meet. He was glad to say that women members, for the most part, were very painstaking and careful in their work. Many of the newly registered women had, however, impressed him as being curiously ill informed on many of those business matters relating to the profession, such as partnership agreements, the purchase of practices, and so forth, and he wished to urge strongly the newly registered women, when contemplating taking any appointment, partnership, or practice, to avail themselves of the experienced advice they could receive, if members of the Union, from the general secretary.

Sir Herbert Waterhouse concluded by expressing appreciation of the services of the general secretary, Dr Neal, and the solicitor, Mr Hempson.

The report of the council and the financial statement for the year 1927 were adopted unanimously. Dr W. S. A. Griffiths, Dr V. A. Jaynes, and Mr F. C. Larkin, the retiring members of council, were re-elected. The auditors, Messrs Lewis Hardy and Co., were reappointed, and authority was given for the payment of the first class railway fares (with expenses if detained for the night) of members of the council attending council meetings from provincial centres. The proceedings concluded with a vote of thanks to the president and council for their services during the past year.

ANNUAL REPORT

In the annual report of the Medical Defence Union, presented at the annual meeting, it was stated that the number of new members elected in 1927 was 1,282, and the net gain

for the year was 853. The total membership was now well over 15,000, and included 1,317 women.

The report refers to a matter in which two members of the Union who were acting as assistant medical officers at a Poor Law institution were involved. They were in charge of a case in which the medical superintendent had suggested there should be an arm-to-arm transfusion of human blood, using a universal donor from among the nursing staff. The only nurse available was aged 18 years, and her parents' consent had not been obtained. When informed of this the medical superintendent said, it was stated, that it did not matter, and that the members were to take it as an order that the transfusion was to proceed at once. The members were advised that they were under no obligation to obey the order of their medical superintendent to perform a definitely illegal act, and that if they obeyed such an order and legal action were taken against them they could not escape liability on the ground that they were acting under his specific direction.

Attention is again called in the report to the advice so often given in connexion with x-ray examinations in cases of injury to a bone or joint, and it is pointed out that some definite record of a patient's refusal to submit to x-ray examination is of the greatest value in resisting claims in which the alleged omission to advise such examination is made the foundation of a charge of negligence. The Union has had to deal with a number of claims against members which would not have arisen if this advice had been followed. One case was heard in the High Court with, the report states, the usual conflict of evidence. The member stated that he had from the very first advised an x-ray examination, and this was flatly denied by the patient. After a hearing lasting several days the jury found in favour of the practitioner, adding a rider that he should have protected himself by calling in another doctor and repeating in his presence the advice to submit to an x-ray examination.

Several members have, it appears, asked for advice regarding inquiries addressed to them by medical officers of health in cases of infant deaths, stillbirths, and maternal deaths. While the council of the Union is aware that these inquiries are the outcome of opinions expressed to local authorities by the Ministry of Health, members have been advised, in view of the ordinary obligations of professional secrecy and of the necessity of safeguarding the legal position of the practitioners concerned, that the detailed information asked for should not be furnished in any case where there is the slightest possibility of the patient being identified. In giving this advice the council has made it quite clear that it is desirable that medical practitioners should assist so far as it may be possible in the compilation of general statistical information.

The report states that many cases of unqualified practice have been investigated during the year. In one case the evidence collected by the Union was brought to the notice of the Director of Public Prosecutions, and proceedings were taken, the offender was convicted of forging a death certificate and sent to prison. In another case ample evidence was obtained, and application was made for a summons, but the offender absconded. Cases handed over to the solicitor during 1927 numbered 90, of these 36 involved charges of negligence, 11 were questions of libel and slander, 5 were complaints of unqualified practice, 10 concerned national health insurance administration, and the remainder were related to a variety of other matters.

England and Wales.

Radium Treatment of Uterine Cancer for the Poor
In London

THE Minister of Health has issued an Order (No. 72810) authorizing the extension of the classes of the poor with whose care the managers of the Metropolitan Asylum District are charged to include poor persons suffering from cancer of the uterus, the object is to enable radium treatment to be provided for such persons who are under the charge of the guardians of the several Poor Law unions in the metropolis. A centre will be provided at the North-Western Hospital of the Metropolitan Asylums Board exclusively for the radium treatment of uterine cancer, and accommodating eight patients at a time, it will be under the charge of Mr. COMBES Berkeley, obstetrical and gynaecological surgeon to the Middlesex Hospital. In a memorandum explaining the scheme it is remarked that the value of radiological treatment of cancer of the uterus must be regarded as fully established, it is recalled that radium has been used for many years at a number of large clinics on the Continent and in America, with excellent results. In

early and border-line cases the results are considered similar to those obtained with surgery, while 15 per cent of those in whom the disease is stated to be inoperable have been found to be alive and well at the end of five years after radium treatment, many others have been granted an increase of life and much relief. Technical and economic considerations render it advisable that the treatment should be concentrated as far as possible. It is proposed that the procedure to be generally employed should be that known as the Stockholm method, in which radium is placed internally in the uterine canal and in the vagina, three separate treatments, each of twenty-two hours' duration, being usual. The patient enters the centre one or two days before the first treatment, and is retained for the second, which is given about a week after the first, so that her first stay at the centre is of about twelve days' duration. She is readmitted sixteen or seventeen days later for about four days for the third treatment, and subsequently returns either to her home or to the Poor Law institution from which she came. It is regarded as most desirable that the patient should, after completing the treatment, return to the centre for examination as often as may be considered desirable by the medical director, the frequency of her visits will depend on her condition, but they may be every six weeks for the first few months and less frequently later. The Metropolitan Asylums Board undertakes responsibility for all transport required in this connexion. Regarding the selection of cases the memorandum emphasizes the point that, while all cases of cancer of the uterus are suitable for treatment by radium, the earlier the stage of the disease the more favourable are the chances of a successful result. Cachectic patients or those with other evidence of septic absorption can often be treated, but the possibility of permanent success is not very great. Patients with a fistula, either vesico-vaginal or recto-vaginal, cannot be accepted, and radium treatment is also contraindicated in patients with definite renal disease. Patients suffering from cancer either of the cervix or of the body of the uterus will be accepted, but in the latter type if the medical director considers that surgical treatment will be more advisable he will communicate accordingly with the medical superintendent of the Poor Law institution. General anaesthesia of short duration will be induced for each insertion of radium. The Metropolitan Asylums Board is prepared, on the advice of the medical director, to admit patients believed to be suffering from cancer of the uterus on clinical diagnosis only, in such cases it is stated to be particularly desirable that there should be no disturbance of the growth for the purpose of diagnosis either by curettage or removal of tissue. It is proposed to publish periodical reports on the work of the centre.

Small-pox among Casuals Cessation of Complete Medical Examination

The Minister of Health has issued a circular (No. 930) to boards of guardians in England and Wales stating that he has been advised that the continuance after September 30th of the medical examination of all casuals admitted to casual wards is no longer necessary. This requirement was imposed upon the Poor Law authorities in the first instance this year by a circular issued in January, and continued at various dates since then. In the most recent communication, while the medical examination is dispensed with, the Minister again calls attention to the need for the examination of every casual by the officer supervising the bathing, with a view to discovering the presence of any skin eruption or other evidence of infection, and for reporting at once to the medical officer any casual found to be so suffering.

Classes for Backward Children in Llanelli

A special report on the education of children in special classes for the dull and backward has been submitted to the Llanelli Education Committee by Dr L. W. Pole, medical officer of health and school medical officer, who calls attention to the need for additional classes and for the employment of specially trained teachers. The report, which has been prepared by Dr Jean M. Mackintosh, covers the period since the specialty classes were instituted

in October, 1923, and gives what information it has been possible to obtain regarding the after-histories of children who have passed out of the scope of the scheme. Four classes have been continued throughout the five years—two for girls and boys, and two for girls. It was hoped originally to provide a special class in each school, but this has not so far been possible. Children selected for the classes are approved both by the head teachers and the school medical department. The tests used for the most part have been Terman's Stanford Revision, Ballard's reading test, and oral addition and subtraction tests, latterly one of the curtato Binet-Simon scales has been employed in place of Terman's test. In practically every case the estimate of educational attainment and grading was in accordance with that of the head teacher. Of the 263 children examined, 227 were found suitable for admission, and 162 were actually admitted, parental consent for the transfer being withheld in the remaining 65 cases. In 61 of these the parents refused to allow the transfer of their children to a special class in another school, while permission to transfer children to a special class in the same school was refused in only 4 cases. At the commencement of the scheme children were admitted between the ages of 7 and 12, and the average age was therefore too high, an effort has lately been made to secure admission at as early an age as possible. With special classes as isolated units to serve districts the pupils necessarily show a wide range of physical age and greatly varying mental age, the classes at Llanelli being composed roughly as to 58 per cent of the total of pupils who are merely dull and backward, 26 per cent being border-line cases or high grade mental defectives, and 16 per cent definite mental defectives. The proportion of low-grade feeble-minded children has been very small, and only a few have proved ineducable. Of the 162 children dealt with 74 are still in the special classes, 50 are now in the ordinary classes, 25 have left school at the age of 14, and most of the others have gone to other districts. An examination of the position of the children now in ordinary classes shows that in most cases their mental capacity, as expressed in the educational ratios obtained by Ballard's tests, has improved substantially. The results of these tests have recently been compared with the results of terminal examinations, and a considerable divergence has been found, Dr Mackintosh states that the two do not appear to have any relation. An attempt to obtain information regarding children who had left school was only partially successful, but in a number of cases it was found that they were in employment or usefully engaged at home. The results are held to justify the gradual extension of the scheme until there is a special class in every school. This would obviate the difficulty now experienced in inducing parents to consent to the transfer of their children to special classes where a change of school is involved. The report, in conclusion, points out that it is essential that teachers in charge of these classes should receive the special instruction provided by the Board of Education for this type of work.

Pollution of Rivers.

The Ministry of Health has issued a circular (No. 922) to local authorities in England and Wales summarizing the first report of the Joint Advisory Committee on River Pollution (to which reference was made in the *Journal* of September 8th, p. 473), and suggesting that steps should be taken to give effect to its recommendations. The Joint Committee drew attention to the fact that under the existing law the Minister of Health, on the application of any county or county borough through whose jurisdiction a river passes, may set up a rivers board to control the whole length of the river and its tributaries so far as it is subject to the Rivers Pollution Improvement Act. It urged that the establishment of such boards would be the first step towards the improvement of the condition of many rivers. The evidence received showed that a body acting throughout the whole or the greater part of a river basin, and specially charged with the duty of preventing pollution, is more effective than a body operating only in a limited area. The Minister of Health therefore reminds local authorities of the provisions of the law

relating to this matter, suggesting that each county council and county borough which is not now a constituent member of a joint body for the prevention of pollution should immediately consider the advisability of making application for the establishment of such a body. It is pointed out that, while action on these lines is principally required in areas where serious pollution exists or is threatened and the problem of dealing with it has already arisen, consideration should not be confined to these areas. The circular emphasizes the importance of realizing that similar action may be necessary in areas which are not at present threatened but may be confronted with the problem in an acute form, since industries which pollute water are being established upon rivers and streams hitherto relatively free from contamination.

New Torbay Hospital

The first patients were received on September 26th at the new Torbay Hospital, which has not yet been formally opened. The hospital has been built at a cost of about £150,000, and has been given by Mrs. Ella M. Roweroff, a member of the Wills family, with whose residence it is connected by a specially constructed road. Occupying an elevated site of about fourteen acres, the hospital overlooks Torbay on one side and faces towards Dartmoor on the other. The x-ray, ophthalmic, and other special departments are equipped on the most modern lines, as are the operating theatres. In the children's ward particular attention has been given to the decoration, while all the wards open on to broad verandas or lawns. The all-electric kitchens are situated at the top of the building. Accommodation for the nursing staff has been provided in a former mansion house adjacent to the hospital site, and connected with the main building by a corridor.

Hunterian Society of London

The next session of the Hunterian Society of London will open on Monday, October 15th, when Dr. A. Westerman will deliver his presidential address on "Gleanings from the Minutes (1807-1928)," at 7.30 p.m. At the meeting on November 5th the subject of the discussion will be "The doctor on the stage" to be opened by Dr. Harold Dearden, Dame Madge Kendall, Sir St. Clair Thomson, Miss Lena Ashwell, and Mr. Ivor Back. On December 3rd the subject for discussion will be "The artificial termination of pregnancy," to be opened by Mr. C. S. Lowe Roberts and Mr. A. McAlister. On January 14th, 1929, the lecturer will be Professor Putti, University of Bologna, Italy. (Title to be announced later.) On March 4th the Hunterian Oration on "Some aspects of the surgery of the spleen" will be delivered by Professor A. W. Sheen. On March 25th the discussion will be on "Blood pressure in health and disease," to be opened by Drs. Halls Dally, Edgar Obermer, and Temple Grey.

Scotland.

Food Poisoning and Preservatives

An address on the causes of food poisoning was given to the Edinburgh Rotary Club on September 27th by Dr. Andrew Rutherford, lecturer in pathology to the Edinburgh Medical School, who referred to the suggestions recently made in newspapers that food poisoning outbreaks were too frequent, and mentioned that doubts had been thrown upon the policy of the Ministry of Health regarding the paratyphoid outbreak in London. There had been, actually, he said, fewer outbreaks this year than previously, and none at all in Scotland, but there had been more publicity. The illnesses were neither new nor mysterious to pathologists in general, or to the medical advisers of the Government, they had nothing whatever to do with the presence or absence of chemical preservatives in food. Potomac poisoning in many was exceedingly rare, and the vast majority of cases of so-called food poisoning were due to living specific microbes, and not to chemical poisons

which in various ways might become implanted in food or drink. Small quantities of boric acid would neither prevent the access of these germs nor kill them if they were present. Referring to the statement that the London paratyphoid outbreak might have been due to cream, Dr. Rutherford said that this implied the likelihood that the cream or milk at some stage had been grossly contaminated by a human carrier of paratyphoid bacilli. The house-fly also played an active part in hot weather in scattering bacteria. Much stricter cleanliness than obtained at present was certainly necessary in the handling, storage, and cooking of food. The recent regulations regarding preservatives tended to lessen, and not to increase, food poisoning outbreaks. It was nonsensical, he concluded, to suggest that because boric acid was absent food became tainted, and so caused poisoning, weak boric acid could not prevent infection by virulent organisms present in food.

General Practitioners and Health Officers

In the introduction to his annual report for 1927, Dr. G. Matthew Fife, medical officer of health for St. Andrews, discusses the relationship of the general practitioner to the health officer in the light of recent developments in the attitude of the public and in medical science. He suggests that the *entente* between patient and doctor is gradually weakening, and attributes this to the disappearance of the family doctor, the influence of the modern hospital and the ubiquitous specialist, and the growth of a more critical attitude on the part of the public towards medical knowledge. People, he believes, are beginning to ask that their doctors should be as efficient at keeping them in health as they have been at treating them in disease—"the health conscience of the nation has been awakened and a measure of aloofness has been engendered which will continue until the present trend of medical thought has been revised and changed." Dr. Fife considers the various factors which have combined to set up a barrier of suspicion between the general practitioner and the health officer. Anxiety may have been engendered in the mind of the former as to his future by the extension of public treatment facilities and the growth of clinics and centres, but such forebodings, he contends, are unwarranted, since any development of State medical service which threatened to weaken the position of the private practitioner would react even more adversely upon the service itself. The general practitioner might be suspicious or obstructive or unsympathetic, but the medical officer of health would be equally misguided if he took no opportunity of getting to know the practitioners of his district, of consulting with them in his schemes, and of endeavouring to gain their willing co-operation. Dr. Fife believes that a new era is dawning in the medical world. The attitude of the public requires, on the part of the general practitioner, a wider knowledge of the facts of health than at present most possess. If he is to be successful he will have to direct his energies more strenuously towards the detection and the meaning of early departures from the normal rather than towards the recognition of late manifestations of disease. The methods and curricula of teaching schools will have to provide as sound a training in clinical physiology as is at present given in clinical pathology, while the medical officer of health must realize that, no matter how perfect his schemes may be, he can never reach the key to the fundamental secret of preventive medicine—the detection of early signs of disease—without the co-operation of the general practitioner in whose hands it lies, for he alone sees the people in health as well as in disease. The future success of medicine and of public health administration, accordingly, depends largely upon the work of the general practitioner. Dr. Fife sums up: "The people cry for enlightenment. It can only be given after medical education has been revised and extended to include health as well as disease as a subject of study, and only when the general practitioner and the health officer work together in the fullest intimacy and trust. Then, and not till then, will the future of medical progress be fully assured and the nation's needs supplied."

Correspondence.

ANAESTHESIA FOR TONSILLECTOMY AND
REMOVAL OF ADENOIDS

SIR,—The very interesting correspondence on the removal of tonsils and adenoids has shown that there are some who believe that this operation should be delicate and unhurried, and that the best anaesthetic for it is ether. I think that to these a description of an inhaler which has been used for three years, and in a good many thousand cases, may be of interest.

The main difficulty in giving ether is to vary the concentration of the vapour from very weak at the start to very strong when deep anaesthesia is needed. With the open method a high concentration can only be obtained by muffling the mask with towels, etc.—a crude, wasteful, and inexact proceeding. Also the ordinary Schimmelbusch mask has the fatal defect for ether that as soon as the fluid is poured on to the convex gauze pad it runs down into its borders, leaving a dry patch through which the patient breathes.

The Clover inhaler, well used, gives a most excellent anaesthetic, but it is expensive, fragile, and difficult to clean, while its proper handling is a very rare accomplishment. Silk's inhaler has the sound principle of retaining the heavy ether vapour where it must be breathed by the patient, by means of a cylinder fitting below closely to the face. The sponge, however, when soaked with ether, is almost impermeable to air, and tends to drip from its lower surface.

My own pattern (made by Allen and Hanbury) is an aluminium "cylinder," 7 inches in height, and shaped to fit the face, with a soft rubber pad at the lower end.

The other is held by an oval gauze pad 7 inches by 5, and at least eight layers thick, preferably hemmed so that it can be washed and used again. This is placed on top of the cylinder, and thrust down into it, on to the bars across the lower end by a smaller cylinder (a) mounted on a handle (A). This gives a flat gauze surface (c) down to which all ether poured into the inhaler runs so that the patient's breath must pass through it, while owing to its flatness there is no tendency to dripping.

I believe this inhaler to have the following advantages:

- 1 It will give a very high concentration of ether with a per centage of CO₂ much as in the Clover inhaler.
- 2 It is very economical, its consumption of ether being only about a third of that of the open method. In one department alone at Great Ormond Street this difference meant a saving of £50 per annum.
- 3 It is simple, cheap, easily cleaned between anaesthetics, and has that priceless quality for hospital equipment of surviving being dropped on a stone floor.
- 4 It does not cover the eyes thus avoiding what I think to be one of the main causes of panic in children.

In using it the main points are:

- 1 Start the induction with a single drop of ether in the inhaler. Anyone who thinks this too little is recommended to experiment on himself.
- 2 Keep the mask closely on the face and as soon as the patient is breathing one strength of ether easily increase it. A fairly wide experience of inducing all types of cases with ether has convinced me that the main causes of failure are starting with too strong a vapour and taking off the mask for no particular reason except to see if the patient is still underneath it.
- 3 As soon as the patient is deeply anaesthetized with dilated pupil and easy breathing hang a weighted hooked mouthpiece on the top of the inhaler and pump ether vapour through it. If

this provokes no coughing, gag the mouth open and hang the tube in it to continue the anaesthetic, again carefully avoiding giving one breath of etherless air.

I have found this method quicker and better than inducing with ethyl chloride and changing to ether, as it avoids that "no man's land" when the patient is coming out of deep ethyl chloride into shallow ether. For com-

parison with the procedure described by Mr Sandiford and Dr Clayton in your issue of July 28th (p 149), I think that with this method an expert operator and anaesthetist can work at the rate of about eight cases an hour, the tonsils being dissected out and all bleeding stopped before the child leaves the table—I am, etc.,

DENIS BROWNE, FRCS,
Resident Medical Superintendent, Hospital for Sick
Children, Great Ormond Street, London.

September 18th.

THE ERECT POSTURE

SIR,—No medical practitioner should miss reading the address of Professor W. Colin Mackenzie, published on September 22nd (p 534), in which the erect posture of man is cited as the structural factor that expresses his essential human nature. This being admitted, the physiological deviations that precede the pathological changes should inevitably be connected with this factor, and as to what this actually implies is suggested in such phrases as "upper limbs free to obey the will of the higher brain," and "the erect posture was the ultimate goal."

We who believe our profession to be as much an art as it is a science, should welcome such phrases, which are too often lacking in the utterances of such purists as comparative anatomists. For if the will towards a goal be the basis of our being, then, corresponding to the anomalies of body functioning, there would be equivalent anomalies of a man's "will to goal," and lack of will can invariably be reduced to terms of mistaken or conflicting goals.

We are learning from all sides that health is wholeness. The terms *will* and *goal* relate to wholeness, since they indicate the whole individual in contradistinction to an aggregate of organic parts. So, then, also must *health* and *wholeness* relate to the meaning of his central structural character of uprightness.

The fact that the erect posture "is maintained and effected by muscular action" places it on a plastic and functioning basis, and herein the looseness of our understanding has let in the osteopaths to the ranks of healers.

In conclusion, let us support the contention that psychology should be a compulsory part of the doctor's equipment, for how else can he acquire the complete understanding of his patient in order to ascertain each sick man's conflict of purpose that replaces the unified goal of the whole man in relation to the human race? In meeting the practical necessities of such psychological training for medical students one can foresee a strong British school of psychology developing by means of the fund of material now at hand leading in an open, free, pragmatic, and in some typically British way to a workable method that could be used by the general practitioner at the bedside of every sick person—I am, etc.,

London, W.1, Sept 25th.

G. C. ADNEY

RAYNAUD'S DISEASE

SIR,—I am desirous of seeing one or more cases of Raynaud's disease, particularly such as are progressing to actual gangrene of the finger-tips, for purposes of investigation, and should be very grateful to any medical practitioner in London who could refer such a case or cases to me—I am, etc.,

THOMAS LEWIS, M D, F R C P

University College Hospital Medical School
Gower Street, W C1, Sept 27th

LIMITATIONS OF MEDICAL BENEFIT

SIR,—Perhaps you will allow me a short personal explanation in response to your leader (September 29th, p 577), which largely concerns me. You say that I do not "seem to be very familiar with the work of general practitioners," and that I have suggested that insurance practitioners give their services "reluctantly and grudgingly."

With regard to the second charge I submit that that suggestion was never made by me. What I did suggest was that panel practitioners were grievously hampered in their panel work as compared with their private work, and that they were uncomfortable under the humiliations imposed upon them by many of the conditions of panel practice, and were anxious, therefore, to relinquish that practice. That thesis has been sustained in numerous letters which I have received during the last few weeks.

With regard to the first statement, I am and have been for twenty-six years the head of a medical department at a teaching hospital, during that long period I have come into very close touch with general practitioners, I have made it a rule, strictly adhered to, to write to every medical practitioner whose name was given me as being interested in the patient sent to the hospital, with as full an account as I could give of my views upon the case sent to me, I have endeavoured to make my department a consultative department—and I think I may claim to have achieved a considerable degree of success in this ambition, as is evidenced by the fact which has been brought out by an examination of my post-book during the past year's work, from which it appears that some four hundred letters have been written to practitioners who have sent patients to my department at the hospital. This is exclusive of my private practice, which, of course, I do not include. Moreover, for twenty-two years I have represented medical graduates, a body which is preponderantly composed of general practitioners, upon the senate of the University of London. By a happy chance for me it was resolved by some of my political opponents to contest my seat upon the senate in 1925, for the first time in twelve years, the vote of confidence which I received at the poll—827 votes, against 281 cast for my opponent—demonstrated, I submit, that the body of general practitioners was satisfied with my services to them. In Parliament I represent a very considerable body of medical constituents, and I hope and I believe that I have won a certain measure of confidence with them also by my intervention in matters of medical interest when they came before Parliament. On all these counts I submit that I have had rather exceptional opportunities of establishing particularly cordial relations with general practitioners.

I am gratified to note that you describe as a "dangerous and undesirable agreement" the contract between the Ministry of Health and the pharmacists, which was the main point criticized in my letters to the *Times*, but which was, somewhat curiously, and perhaps prudently, ignored by the official apologists for the British Medical Association, Dr Brackenbury and Dr Cox. Personally I think that your leader minimizes the dangers of this agreement, nor can I agree with your statement that these arrangements "do not in fact in any way restrict the liberty of an insurance practitioner in prescribing whatever he thinks it necessary for his patient to have." That opinion conflicts with the view expressed in the report of the British Medical Association Insurance Acts Committee,¹ where it is said "The new arrangements between the pharmacists and the Ministry of Health, which were reported to the last annual conference, affect insurance

practitioners to some extent. The amount available per insured person for drugs and appliances is now restricted" (the italics are mine). The Conference of Panel Committees probably knew what it was talking about when it recorded a unanimous resolution that the contract was "against public policy." I have before me a copy of a circular from a pharmaceutical committee to pharmacists upon the panel in which the following sentences are found:

"Do not forget that economy is absolutely necessary if chemists are to maintain their rate of payment. Money saved now remains in the Drug Fund for distribution to chemists." Report to the Secretary of your Pharmaceutical Committee all instances of extravagance in prescribing of whatever kind. Report to the Secretary of your Pharmaceutical Committee all the cases you have of regular drug takers under the Act giving name of patient and of doctor with period over which supplies have been obtained from you. Remember that if you express a wish to that effect your name need not be used in connexion with any reports you make.

I submit that Dr Gordon Ward's description, in his letter in the *Times* of September 24th, of the effect of this arrangement is nearer the facts than your statement. Dr Gordon Ward's description runs "The Drug Fund, strictly limited in amount, has to provide a working profit for the chemists first, and the amount of medicine available for the insured is strictly conditioned by what is left over." Your presentation is "The arrangement is that the pharmacists take the whole of the residue of the medical benefit fund after all other claims upon it have been satisfied, and in return for this total sum undertake to supply insured persons with whatever is properly prescribed by insurance practitioners." Surely it is obvious that it is now the chemist who is the judge of what is "properly prescribed", if the chemist can, as the above extracts show he is encouraged to do, report to his Pharmaceutical Committee "all instances of extravagance in prescribing," and if the result of this secret report is to subject the practitioner to endless worries over a long period of months and to the probable infliction of a fine at the end of that period, the practitioner is very effectively discouraged from going beyond the formulary considered "proper" by the chemist.

Further, I cannot agree with your dictum that there was "no other means of escape" for the Ministry of Health than this "dangerous and undesirable agreement." The escape was from the unwelcome demonstration that the insurance Drug Fund had long been insolvent, the scheme adopted was an unworthy evasion of the facts, which should not have been countenanced by those representatives of the British Medical Association whom the Ministry of Health apparently consulted and whose approval it obtained. Probably more will be heard of the agreement when Parliament reassembles, and it is, I think, to be hoped that those who speak for the medical profession should make it quite clear that this agreement is not in accordance with their wishes or with their opinions of what is right. The misfortune of the National Insurance Act is that it originated as an electioneering dodge and has never lost its political complexion. The "ninepence for fourpence" slogan which started it upon its meretricious way was an unhappy forecast of the sham which, in the opinion of many, that system of health insurance under its current provisions remains. That is not because the general practitioner is incapable of working it. In my letter to the *Times* I said expressly, "The British general practitioner is easily the best trained practitioner in the world." It is because his professional liberty is in effect controlled by a political bureaucracy and, as a result of the recent arrangements, still further controlled by the Retail Pharmacists' Union.

In Dr C O Hawthorne's interesting medical essays, which I have read with great pleasure, certain suggestions are made for the co-operation of local practitioners with the voluntary hospitals in their neighbourhood. I, too, would like to see this co-operation become much more effective and closer than it is at present, although I do not think Dr Hawthorne's solution is practicable. My suggestions—too long to detail here, but which I hope to unfold in another place—are for a complete revision of the methods of health insurance. Very briefly, the germ of my suggestions is that the co-operative effort to secure

¹ *British Medical Journal Supplement*, August 25th 1928.

prevention of sickness, which is now the real service given to the nation by the voluntary hospitals, should be extended to include panel patients and panel practitioners who are not now included in that scheme—I am, etc.,

London W Oct. 1st

D GRAHAM LITTLE

* Neither the British Medical Association nor its Insurance Acts Committee has ever given its approval to the arrangement with the pharmacists to which reference is made in Dr Little's letter. It was not "in accordance with the wishes" of either or "in accordance with their opinions of what is right." They have taken several opportunities of making this clear, and Dr Little is again under an entire misapprehension.

THE FALLING BIRTH RATE

SIR,—Interesting as were the contributions to the discussion at Cardiff on our falling birth rate and its class incidence (printed in the *Journal* of September 15th), surely the contributors all missed the essential point—the old Darwinian truism that the fittest survive, fitness meaning fitness to survive in a given environment, the world having no relation to intellectual power, moral worth, or physical efficiency. The dog's fleas are as fit as the dog so long as they have a dog to feed on, and no longer. The term is relative, depending on the environment as much as on the organism. To call the Eskimo or the negro "fit" is to leave a sentence unfinished. Each is fit in his own surroundings, neither would survive a year under conditions where the other flourishes. Further, environment is continually changing—to the advantage of some types and the destruction of others. The reindeer roamed in immense herds over England when the country was closer to the Glacial Age. He became unfit, and consequently extinct, not because he degenerated, but because his environment changed.

Civilized man's environment has changed immeasurably in the last century, social reform being the chief factor that has changed it. In the bad old days every heaving lung by its own tail, vice was unchecked, venereal disease untreated, and alcohol easier to obtain than food. The feeble-minded weakling, the drunken waster stood little chance of rearing children, though the fecundity of such people was no doubt high. Those who could exercise sobriety, self-control, and energy raised families and increased in numbers. Eventually they became numerous enough to form a culture and force the outward semblance of their culture upon the whole body politic.

With civilization comes inevitably the reversal of those laws that bring civilization into being. The feeble-minded and degenerate immediately become—in a Darwinian sense—the fit. They have a high fecundity, the State sees to it that they have a low infant mortality. True, their earning capacity is small, but that is immaterial so long as they can live a parasitic life on the rest of the community. They are as fit as the dog's fleas, as fit as the dog-fitter, perhaps, than the dog who lacks the sense to scratch his fleas off him.

Meanwhile, a large and growing number of intelligent persons are ceasing to believe in the future of the race. Where there is no vision the people perish—excepting such types as desire only the gratification of animal desires and the avoidance of work. As it was in Rome, the parasite class will increase until their host can no longer make blood fast enough to content them. And so the world will continue to go, until it is realized that the duty of a State to provide sustenance for every child born carries with it, as a corollary, the duty of decreeing what children shall not be born—I am, etc.,

H M STEPHENSON, M R C S, L R C P

Chilpenham Sept. 24th

SIR,—In Lady Barrett's paper on the falling birth rate, published on September 15th (p. 485) there occurs the passage, "the [birth control] clinics where they [rubber caps] are in use have no records of systematic examination of the cervix with speculum to ascertain whether cervicitis occurs."

At the North Kensington Clinic, 12, Telford Road, Ladbroke Grove, every patient on her first visit receives a

full pelvic examination bi-manually, and with a speculum, this is recorded in detail. Subsequently, at her regular six-monthly visits, she is re-examined, and any change recorded. In this way we are acquiring detailed records of the effects of rubber caps and spermaticides.

Lady Barrett states that she has found cervicitis "a frequent result" of the use of rubber caps. We would like to know how she ascertains that the cervicitis was not present before the patient began the use of caps?

It is our experience that when a patient has been fitted with a suitable cap no pathological conditions have been found to result.—We are, etc.,

INTRATHORACIC AND INTRAPERICARDIAL PRESSURE

SIR,—May I correct a small misunderstanding in the review of my booklet, *A New View of the Intrathoracic and Intrapericardial Pressures in Man*, which appeared on page 532 of your issue for September 22nd?

From the sentence in the review beginning "He further argues, supporting the theory of Kroetz, that because the fibrous pericardium is inextensible the intrapericardial pressure must be that of the atmosphere" the erroneous impression is obtained that my view of the pericardial pressure is based on the paper by Kroetz quoted in my pamphlet. I regret that a phrase of mine in the booklet admits of such an ambiguity, but I wish to claim as my own the theoretical deductions from which I developed a new synthesis of the pressure conditions in the thorax.

I am indebted to Kroetz only for the perplexity which led me to consider *de novo* the physics of the chest—I am, etc.,

Titchmarsh Sept. 25th

ALFRED KENDREW, D M OXON

NATIONAL DEATH RATES

SIR,—Reading over both Professor Moorhead's article on acute nephritis and the *Journal's* review of it I was struck by the absence of any commentary on the respective general death rates for the years 1922-26 in England and Wales, and the Irish Free State. For this period of five years 314,829 deaths were registered in the Irish Free State and 2,231,445 in England and Wales. The population of the Irish Free State is 3,365,000, and of England and Wales 37,885,242. According to population one would expect to find approximately one death in the Irish Free State to correspond with eleven deaths in England and Wales. From the figures submitted by Professor Moorhead the rate is one to seven. Admitting the accuracy of the figures, what accounts for the very high death rate in the Irish Free State? The death rate from acute nephritis is more striking still, the proportion being roughly one in five—I am, etc.,

DEMENTIA PRAECOX IN PARSEES

SIR,—Lieut.-Colonel Jagoe Shaw, in his article in your issue of September 29th (p. 566) lays great stress on "inbreeding" as a cause of the high incidence of dementia praecox among the Parsees of Bombay. But in the same article he seems, inadvertently, to have demonstrated a still more important cause—namely, "Western" education and civilization generally. The Parsees, he tells us, are the most Europeanized of the natives of India, they are next to them the Anglo-Indian community, are the classes most affected by dementia praecox. This condition is very much rarer among Hindus and Mohammedans, who are at a "lower" stage of civilization, where it does occur in these two latter groups it is "mainly in the educated classes or rather in the persons of boys who have undergone the intensive system of education or memory training by which only can an Indian hope to obtain admission to Government service."

The common factor, then, in all these cases is not inbreeding but Western education, hence we may look on

thus, with the cramming and standardizing method which characterizes it, as being the main cause of the brooking up of these young people's minds ("schizophrenia" is Greek for "split mind"). If we are to advise the Puseys against anything, it is rather against their too wholesale acceptance of Western civilization, especially on its educational side. But better still if we take the warning to ourselves, for I believe it will be found that in our country dementia praecox is increasing in direct ratio with the increasing inroads of the central Government into the liberties of the individual—which inroads, by the way, are carried out equally under the slogans of imperialism and socialism—I am, etc.,

North Queensferry Fife Sept 30th

ARTHUR J BACOCK

THE PETTIGREWS

SIR,—Both "H R" and Mr Munhead Little may like to know that W Vesalius Pettigrew was a member of the teaching staff of the School of Anatomy adjoining St George's Hospital from 1842 to 1851. He assisted Samuel Lane with the lectures on anatomy, physiology, and surgical anatomy, while the practical anatomy and the demonstrations were conducted by him with the aid of a demonstrator. He also acted as secretary of the medical committee of the school for most of the time. His father was a most versatile person, and among other works was the author of the following books, all of which are now quite scarce: *A History of Egyptian Mummies*, quarto, 1834, *Medical Portrait Gallery*, 4 volumes, royal 8vo, usually bound in two volumes, undated, *Medical Superstitions*, 8vo, 1844. His *Chronicles of the Tombs* was brought out in the Bohn series in 1864, I do not know of a better collection of epitaphs than this—I am, etc.,

London W Sept 28th.

R R JAMES

SIR,—I am not in touch with the files of the *Journal* of the date mentioned by Mr Munhead Little, but I have some faint recollections of having been one of the correspondents alluded to by him. Moreover, Thomas Joseph Pettigrew was known to my family and attended me professionally in my early childhood. I have no distinct remembrance of him, but I still have a few small relics of ancient Egypt which were once in his possession, and many years ago I added his bookplate to my collection of the bookplates of medical men. It is armorial and has a Greek motto, from Lucian, beneath his name, to which the only suffix is "F L S." I remember being told that he was the first to unroll a mummy in this country, and that the meeting at which he had undertaken to do this had to be adjourned in order to complete the operation, the magnitude of which was then as yet unrealized. Thomas Joseph Pettigrew was acquainted with the Egyptologists, Thomas Young and Champollion, and with John Coakley Lettsom (born in 1744), whose life he wrote. It is a long span between that date and the present—I am, etc.,

London Sept 30th.

P

Obituary

DR JULIUS MOORE, who died at Enfield on September 25th in his fifty-sixth year, after a short illness, was born at Rochester, Kent, and received his medical education at Guy's Hospital. He obtained the diplomas MRCS, LRCP, and graduated MB Lond, in 1897, proceeding MD four years later. He had been resident in Enfield for many years, and was surgeon to "Y" Division of the Metropolitan Police, acting also as medical officer to the General Post Office and the Metropolitan Water Board. During the war he served with the Royal Army Medical Corps. Dr Moore was a Fellow of the Royal Society of Medicine and a member of the British Medical Association. A colleague writes: After practising for a short time at Farnborough, Hants, Dr Moore removed to Enfield in 1902, where his great ability and lovable disposition soon gained him a very large practice—too large, indeed, for there is no doubt that his untimely

death was in great measure due to his self-sacrificing devotion to the interests of his patients. Dr Moore represented the finest type of general practitioner, beloved by rich and poor, and adored by children. Of late years in the midst of his busy life he found time to specialize in ear, nose, and throat work. He devoted himself largely to the Enfield War Memorial Hospital, of which in recent years he became medical manager. His quiet unassuming manner hid a warm heart, to which none ever appealed in vain. He was held in the greatest affection by all his colleagues, to whom he was always a loyal friend. The funeral service at St Mary's Church, Enfield, which was packed to overflowing, was a remarkable tribute to the love felt for him by all classes. He leaves a widow, but no children.

We regret to announce the death of Dr GEORGE FINDLAY of Brailes, Banbury, which occurred with tragic suddenness on September 16th, in his sixty-fifth year, while he was in attendance upon a maternity case. He was born in Aberdeen, and received his medical education at that university, graduating MB, CM with honours in 1886. He subsequently studied in Vienna, Berlin, and Paris, and was for a period assistant medical officer at James Murray's Royal Asylum, Perth. Nearly forty years ago he settled in Brailes, Warwickshire, where he built up an extensive practice in a scattered hilly district, which made heavy and continuous demands upon him. He was medical officer for the Brailes district of the Shipton-on-Stour union, and since 1914 had also been medical officer of health for the Brailes, Shipton-on-Stour, and Clipping Campden rural districts; he was also an honorary surgeon to the Ellen Badger Hospital, and rendered very valuable service to the St John Ambulance Brigade in the Brailes area. During the war, in addition to relieving a colleague for military service, he undertook the medical charge of a Belgian refugee colony and of a group of German war prisoners. Throughout his life Dr Findlay played an active part in the public life of the community in which he lived; he was for many years vicar's warden at St George's Church, Brailes, and was keenly interested in its restoration. He gave his support freely to various social and sporting organizations, and was one of the prime movers in the establishment of the Brailes village institute at the end of last century. Dr Findlay was held in high esteem by all classes, and notably by the poor, not only on account of his professional skill and ungrudging labour, but also for his personal attractiveness. He was twice married, his second wife dying about four years ago; he is survived by a son of his first marriage, Dr George William Marshall Findlay.

MR THEODORF STEWART CHAMBERS, who died at Wentworth, near Durban, South Africa, on May 25th, on his seventy-eighth birthday, was born in Jamaica and received his medical education in Edinburgh. He obtained the diplomas LRCP, LRCS Ed in 1873, and was admitted to the Fellowship of the Royal College of Surgeons of Edinburgh seven years later. In 1889 he went to South Africa, and served for a time at the New Somerset Hospital, being afterwards appointed district surgeon at Hanover in Cape Colony. Later he was for nine years district surgeon in the native reserve at Mapumulo in Zululand, and more recently was engaged in private practice at Wentworth in Natal. Mr Chambers, who was a member of the British Medical Association, is survived by his widow and one son.

DR ALICE DEBORAH HICKLING, whose death occurred at Hong-Kong on September 22nd in her fifty-second year, was the daughter of a missionary, the Rev James Sibree, DD, who at the age of 92 is now living at Bromley, and the wife of Mr C C Hickling. She was born in Madagascare, and was educated at Oxford and at the London School of Medicine for Women (Royal Free Hospital), and obtained the Scottish triple qualification, LRCP, LRCS Ed, LRFPS Glas, in 1901. After acting for two years as house surgeon at the Sanatorium

for Consumptives, Clare, Suffolk, she became an inspector of midwives, subsequently proceeding to Hong-Kong, where she was employed in the Government service as assistant medical officer in charge of native hospitals. She was also honorary medical officer to the Victoria Nursing Division there, and during the war received the M.B.E. for her services in connexion with this organization.

The Services

DEATHS IN THE SERVICES

Major Abdus Sattar Khan, Indian Medical Service, died at Gaya on July 20th, aged 46. He was born in May, 1882, the son of the late Hosein Khan extra assistant commissioner in the Central Provinces, was educated at the Calcutta Medical College, where he graduated as L.M.S. in 1904, and at Guy's Hospital, and took the M.R.C.S. and L.R.C.P. Lond. in 1907. Entering the I.M.S. on August 1st, 1908, he became major after twelve years' service, but was placed on the temporary non-effective list, on account of ill health, from March 8th, 1922 to July 15th 1924. He served in Mesopotamia during the recent war. After his return to full pay he was appointed to the command of this military hospital at Delhi. He leaves a widow, who received the Order of the Kaiser-i-Hind in this year's birthday honours for welfare work among women and children at Delhi.

Major Ronald Ernest Todd, R.A.M.C. (ret.), died suddenly in London, on August 5th of heart failure following pneumonia, aged 45. He was born on August 18th, 1882, educated at St. Thomas's, and took the M.R.C.S. and L.R.C.P. in 1907. Entering the R.A.M.C. as lieutenant on July 29th 1907, he became major after twelve years' service, and retired last year, on July 29th, as soon as he had completed twenty years' service. He was seconded for service in Egypt on November 1st, 1911, and remained in that country up to August, 1916. He served throughout the war of 1914-18, and was twice mentioned in despatches—in the *London Gazette* of June 21st, 1916, and of December 21st, 1917.

Major William Graeme Donroche McCall, M.C., R.A.M.C., died in Portwilliam, Calcutta, on August 9th, aged 38. He was born on June 3rd 1890, the elder son of Mr. and Mrs. McCall of Houth county Dublin, and educated in Dublin in the School of the Royal College of Surgeons, Ireland, taking the Irish double qualification in 1915. Immediately after qualifying he entered the R.A.M.C. as a temporary lieutenant on August 29th, 1915, becoming temporary captain after a year's service. He took a permanent commission as captain on February 2nd, 1919, and became major on August 2nd, 1927. He served through the war of 1914-18 from 1915 to the end, and gained the Military Cross on July 26th, 1918, with a bar on October 25th, 1918.

Universities and Colleges

UNIVERSITY OF LONDON

Dr. E. B. VERNY, Professor of Pharmacology in the University, will give a course of six lectures on urinary secretion, at University College, Gower Street, W.C.1, on Mondays, October 15th, 22nd, and 29th, and November 5th, 12th, and 19th. Admission to the lectures is free, without ticket.

The Simon Lecture on laryngo-rhinology and general medicine will be given by Professor Markusz Hajek, Professor of Oto-rhino-laryngology in the University of Vienna, in the Barnes Hall of the Royal Society of Medicine on Thursday, November 1st, at 5 p.m.

Provided that there be a candidate of sufficient merit a Paul Refting prize of £30 will be awarded on December 3rd for the best essay embodying the result of some medical research work carried out by the applicant. Candidates must be matriculated students who on June 1st preceding the award were studying in one of the schools of the University in the Faculty of Medicine, or graduates of the University who on the same date were of not more than five years' standing from the date of taking their first degree, and who are or were students in such school.

VICTORIA UNIVERSITY OF MANCHESTER

The following candidates have been approved at the examination indicated.

D.P.H.—Part I: M. Naughton, Josephine Wainman. Part II: George I. Brodie, T. S. Haddon, H. Harrison, M. Naughton, Jean M. Orkney, J. S. Smith, Margaret Sproul.
DIPLOMA IN PSYCHOLOGICAL MEDICINE—Part I: H. A. Palmer.

Medical News.

THE seventh annual dinner of the London Branch of the University of Bristol Association of Alumni will be held on November 2nd, at 7.45 p.m., at the English Speaking Union Club, Dartmouth House, Berkeley Square, W., with Mr. Stanley H. Badcock, pro-chancellor of the University of Bristol, in the chair. Tickets may be obtained from Dr. Elizabeth Casson, Holloway Sanatorium, Virginia Water.

THE medical committee of the Royal Dental Hospital School of Dental Surgery will be "At home" to all past and present students from 10 a.m. to 5 p.m. on Saturday, October 20th, an invitation to be present is extended to all medical practitioners. In the morning the various departments of the hospital and school may be inspected, and demonstrations will be given by members of the staff and lecturers, in the afternoon orthodontic and other cases of special interest will be shown.

THE next meeting of the Biochemical Society will be held in the Biochemical Laboratory, Cambridge, to-day (Saturday, October 6th) at 2.30 p.m. Sir F. G. Hopkins will contribute a paper on the centenary of Friedrich Wöhler's synthesis of urea, various other communications will also be read.

THE Schorstein Memorial Lecture will be delivered in the Bearstead Clinical Theatre of the London Hospital Medical College by Dr. Cecil Wall, on Friday, November 2nd, at 4.15 p.m., the subject will be expectoration. Members of the profession are invited to attend.

A SPECIAL meeting of the Institution of Heating and Ventilating Engineers will be held on October 9th, at 12, Russell Square, W.C.1, at 6.45 p.m., when Dr. H. M. Vernon will give an address on methods of heating and ventilating schools and their influence on health.

A MEETING of the Medical Officers of Schools Association will be held at 11, Chandos Street, W.1, on October 19th, at 5 p.m., when Surgeon-Commander Sheldon F. Dudley, R.N., will read a paper on microbial dissemination in schools.

A MEETING of the Royal Microscopical Society will be held in the lecture hall at 20, Haver Square, London, W.1, on Wednesday, October 17th, at 7.30 p.m., papers will be read by Mr. J. E. Barraud, F.R.S., and Mr. F. V. Welch on "An electrically heated warm stage with compressor for use with high power objectives", and by Professor E. Ghosh on "Two new plants from sewer water". The biological section will meet on Wednesday, November 7th, in the library.

A MEETING of the Optical Society will be held at the Imperial College of Science and Technology, on October 11th, at 7.30 p.m., when papers will be read on lenses and equipment for ultra violet photography, old English objectives, and the development of spectacles in London from the end of the seventeenth century. Further information may be obtained from the assistant secretary of the Optical Society, 1, Lower Gardens, Exhibition Road, S.W.7.

MEETINGS of the Child Study Society will be held at the Royal Sanitary Institute, 90, Buckingham Palace Road, S.W.1, on October 11th and 25th, and on November 8th, at 6 p.m. At the first of these Dr. Letitia Fairfield will lecture on child study in America, and on October 5th Dr. C. J. Thomas will speak on child study and the health of the child. The subject of the third meeting will be music and the child mind.

A CONFERENCE on housing and health will be held in the Town Hall, Windsor, on Friday, October 19th, at 8 p.m., when Dr. J. J. Paterson, M.O.H., Maidenhead, will preside. The speakers will be Dr. William Butler, L.C.C., on "The New House", and Miss Joan Sunderland, house property manager of the Ecclesiastical Commissioners, on "The Old House".

POST GRADUATE instruction in clinical pathology, bacteriology, and biochemistry can be obtained at the Elizabeth Garrett Anderson Hospital by medical women during October and November, particulars will be sent on application to the secretary of the hospital.

THE Fellowship of Medicine has arranged several clinical demonstrations for the coming session. On Monday, October 9th, at 2.30 p.m., Mr. H. W. Carson will demonstrate operations at the Prince of Wales's Hospital, Tottenham, and on the same day, at 4 p.m., Dr. Gerald M. Slot will speak on rheumatism at the Royal Waterloo Hospital. On Wednesday, October 10th, at 4 p.m., Dr. S. H. Daukes will give a demonstration at the Wellcome Museum of Medical Science, his subject being the value of a synoptical museum of medicine for post-graduate study. These demonstrations are free to medical practitioners. From October 8th to 20th the Chelsea Hospital for Women will hold a course in gynaecology during the afternoons and one or two mornings. From October 8th there will be a three weeks intensive course at

the Central London Throat, Nose and Ear Hospital including clinical, practical operative, and pathological sections. The clinical course may be taken separately or in conjunction with one or both of the other parts. On Tuesdays and Thursdays, from October 9th to November 1st, there will be a series of lectures demonstrations at the London School of Tropical Medicine by Dr Carmichael Low and Dr Phillip Manson-Bahr. From October 15th to 27th there will be a special morning course at the Hospital for Sick Children. Professor Louise Molloy will give four lecture demonstrations on antenatal treatment at the Royal Free Hospital, beginning on October 26th. At the Hampstead General Hospital there will be a course for general practitioners from October 29th to November 10th. Copies of all syllabuses, information relating to other post-graduate study in London under the Fellowship of Medicine scheme, and specimen copies of the *Post Graduate Medical Journal* may be obtained from the Secretary, 1, Wimpole Street, W 1.

ISLINGTON Health and Baby Week commenced on Monday last and throughout the week special lectures on appropriate subjects were delivered at various centres throughout the borough. Leaflets giving details of the local health organization and containing simple health hints were distributed.

H R H PRINCE ARTHUR OF CONNAUGHT, at the annual Middlesex Hospital dinner, held at the Savoy Hotel on October 2nd, announced that a friend of the hospital had come forward with a gift of £125,000, to be used for the purpose of providing accommodation for paying patients. It had been decided that such patients should pay a flat rate to cover maintenance, operation costs, and all other services of the hospital, and that no profit should accrue from them to the hospital itself. It was announced later that this benefactor is Lord Woolavington.

A NEW wing at Crews Cottage Hospital was opened on September 29th by Princess Mary Viscountess Lascelles. Towards the total cost of £20,000 a sum of £13,000 has already been subscribed, including a contribution of £2,500 from the London Midland and Scottish Railway Company.

Dr R P GARROW has been appointed Medical Officer of Health for Hornsey in succession to Professor W W Jamieson, who has been appointed to the chair of public health in the University of London, tenable at the London School of Hygiene and Tropical Medicine. Dr Garrow has been M.O.H. for Obesterfield since 1921, and was formerly assistant M.O.H. at Ealing.

THE annual Noech prize for the best paper read before a branch or group of the Society of Medical Officers of Health has been awarded for the session 1926-27 to Dr J A H Brincker, a senior medical officer of the London County Council, whose paper on "The case for diphtheria immunization" was read before the metropolitan branch of the society.

THE second Peruvian Congress of Medicine will be held at Arequipa in the second week of November, under the presidency of Dr Edmundo Escamé, when the following subjects among others will be discussed: small pox in Peru, typhus in Peru, leishmaniasis and blastomycosis in Peru, the medical fauna and flora of Peru, the medical geography of Peru, the problem of cancer in Peru, the racial problem in Peru, prophylaxis of venereal diseases in Peru, alcoholism and other toxic psychoses, pharmaceutical legislation, and anaesthesia in odontology.

THE thirty-fourth Italian Congress of Internal Medicine will be held at Rome from October 12th to 15th, when the following subjects will be discussed: tumours of the spinal cord (in conjunction with the Italian Society of Surgery), introduced by Professors F Schaper, L Dominici, and M Gortan; undulant fever and Bang's bacillus, introduced by Professor U Gabbi; diabetes and diuretics, introduced by Professors L Ferrarini and V Ghirelli; and emotional cardiac disorders in relation to military service, introduced by Major G D D Ambrosio.

UNDER the name of Journées Médicales de Bordeaux a congress will be held at Bordeaux from November 4th to the 7th simultaneously with the celebration of the fiftieth anniversary of the foundation of the faculty of medicine.

IN connexion with the celebration in December of the centenary of the University of Cairo a tour is being arranged through Venice, Brindisi, and Alexandria on the outward journey, and Rhodes, Athens, and Corfu on the return. The programme and other information may be obtained from the editor of the *Wiener medizinische Wochenschrift*, Porzellan gasse, 22 Vienna IX.

THE League of Nations Health Organization has issued in pamphlet form a report of a meeting of its Conference of Health Experts on Infant Welfare, which was held in London early in July. Dame Janet Campbell took the chair, and representatives of the United States, France, Holland, Germany, Norway, and Austria were present. The conference considered the results of an inquiry into infant mortality,

based on a study of all infant deaths in selected districts during a period of twelve months. Three principal causes accounted for the largest proportion in all countries—dead births and pneumonia, birth, respiratory diseases, and gastrointestinal affections. It was considered that the first of these might be due to the absence of adequate pre-natal and obstetrical service, or to lack of supervision during pregnancy, and undue obstetrical interference, but it was deemed inadvisable to express further opinions until the material collected had been analysed and summarized in the final report. The conference decided that separate reports should be prepared for each country on a uniform plan, and that the members should prepare detailed suggestions for further inquiry into problems of infantile mortality which have emerged from the studies already made. A proposal for an inquiry to determine the etiology of rickets and to reach conclusions regarding the prophylaxis of this disease was prepared for submission to the Health Committee of the League.

Dr LEVADITI of the Institut Pasteur, Paris, has been elected a member of the Académie de Médecine.

Dr FREDERICK VON MÜLLER, professor of medicine at Munich, and Dr Karl von Noorden, professor of medicine at Frankfurt, have recently celebrated their seventieth birthdays.

By permission of King Faisal the designation of the Iraq College of Medicine has been changed to the Royal College of Medicine, Baghdad. The dean of the College is Dr H. C. Sutherland.

THE following appointments have recently been made in foreign faculties of medicine: Dr Kirch of Würzburg, professor of pathology at Erlangen in succession to Professor Hirsch; Dr Dietrich of Cologne, professor of pathology at Tübingen in succession to Professor Schmincke; Dr A. Jency of Szeged, professor of pathology, and Dr J. V. Daranyi, professor of hygiene, at Szeged; Professor Rudin of Basle, director of the genealogical department of the Psychiatric Research Institute at Munich; Dr Magyarot, professor of dermatology and syphilis at Montpellier; Dr Moog, professor of chemistry and toxicology at Toulouse; Dr Hermann Dold of Berlin, professor of hygiene at Kiel; and Dr Georg Joachimoglu of Berlin, professor of pharmacology at Athens.

DURING the first four months of this year there were 93 deaths from small pox in Japan.

THE high death rate among infants and young children is a striking feature of the report for 1927 of the Department of Health of the Government of Palestine. Deaths in the age groups 1 month to 5 years account for 57.76 per cent of the total mortality, while only 18.20 per cent occur in the age groups 5 to 50 years. There was a considerable expansion in facilities for the treatment of infants during the year, and attendance at infant welfare centres has improved as the mothers have gained confidence in them. Six new centres have been opened, making a total of thirty-one in operation at the end of the year. Infantile mortality varied considerably with the religious divisions of the population, being 115.3 per 1,000 among Jews, 187.2 among Christians, and 216.7 among Moslems. The figures reflect the work of the six infant welfare centres established by the Jewish population, this class of work being limited to the towns and Jewish rural settlements, while the Arab village population of nearly 500,000 remains untouched. Efforts are being made to provide suitable centres. A committee of the Supreme Moslem Council supports a number of beds for Moslem women in the Princess Mary wards of the Government Hospital in Jerusalem, and defrays the cost of training Moslem pupil midwives.

THE forty-fourth annual report of the National Society for the Prevention of Cruelty to Children shows that in the year ended March 31st the society was called upon to investigate 39,774 cases, involving the welfare of 98,158 children. A large number of crippled and deformed children have been dealt with in orthopaedic cases alone 316 children have been successfully operated upon, and in all 1,762 children have been relieved of physical disabilities and deformities. Two ambulances maintained by the London Medical Branch have been employed in conveying children to and from the out-patient departments of the various hospitals. In persuading parents to secure regular medical treatment for their children useful work has been done by the society's women inspectors, who have also devoted themselves, after special training for the purpose, to seeing that instructions given at the hospitals are carried out.

Dr ADALBERT CZERNY, professor of children's diseases at Berlin, has been nominated an honorary member of the American Pediatric Association, Dr Max Rubner, professor of physiology at Berlin, an honorary member of the Interstate Post-Graduate Medical Association and Dr Theodor Axenfeld, professor of ophthalmology at Freiburg an honorary member of the Hungarian Ophthalmological Society.

Letters, Notes, and Answers.

All communications in regard to editorial business should be addressed to **The Editor, British Medical Journal, British Medical Association House, Tavistock Square, W.C.1**

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the **BRITISH MEDICAL JOURNAL** alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names not necessarily for publication.

Authors desiring **REPRINTS** of their articles published in the **BRITISH MEDICAL JOURNAL** must communicate with the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W.C.1, on receipt of proofs.

All communications with reference to **ADVERTISEMENTS** as well as orders for copies of the **JOURNAL**, should be addressed to the Financial Secretary and Business Manager.

The **TELEPHONE NUMBERS** of the British Medical Association and the **BRITISH MEDICAL JOURNAL** are **MUSEUM 9361, 9352 9363, and 9364** (internal exchange, four lines).

The **TELEGRAPHIC ADDRESSES** are:

EDITOR of the **BRITISH MEDICAL JOURNAL**, *Aitology Westcent, London*

FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.) *Articulate Westcent London*

MEDICAL SECRETARY, *Mediscera Westcent London*

The address of the Irish Office of the British Medical Association is 18 South Frederick Street, Dublin (telegrams *Basillus Dublin* telephone 62550 Dublin), and of the Scottish Office, 7, Drumshugh Gardens, Edinburgh (telegrams *Associate, Edinburgh*, telephone 24361 Edinburgh).

QUERIES AND ANSWERS.

HYPERPLASIA OF THE LEGS.

"P. A. R. K." asks for advice in the treatment of a general enlargement of the soft tissues of the legs from the knee to the ankle. The patient is a woman, aged 34 who is otherwise healthy, she is slightly built and tall, and the legs are a great disfigurement. The condition is of several years duration and is attributed to severe chilblains on the legs, caused by repeated chilling of the feet and legs for long periods followed on each occasion by standing in front of a hot fire. There is no pain or oedema and the skin is healthy. There are no varicose veins no affection of the joints, and no flat foot, the feet are not affected. The condition is practically symmetrical. Massage, Souché baths, artificial sunlight, and manipulation by an osteopath ("in case the ankle-bone was displaced") have been tried without effect.

SCALP ITCHING

"PUZZLED" asks for advice as regards the treatment of a case of intense irritation of the scalp. The itching is confined to the top of the scalp, and there is no dermatitis to account for it. The urine is free from sugar and albumin, there is no history of jaundice. Beyond scurf and a small spot of purple on the head probably caused by the frequent scratching there seems to be no reason for the condition. Bromides have been tried with little success.

HEALTH AND DUPLICATING MACHINES

"J. O. C." asks whether there is any evidence that the constant use of a duplicating machine is prejudicial to health. He has a patient a girl who is thus employed, she complains of irritation of the eyes and throat which she attributes to her work. The ink used contains in neutral solution castor oil commercial sodium isotate, hloven rape, and small amounts of carbon black, Prussian blue and violet lake. The stencil is coated with gelatin, to which is added a small amount of formaldehyde to prevent rotting. Girls who work in a room with 20,000 drying sheets do not suffer in any way, nor does the man who mixes the ink.

. Omission of the formaldehyde (substituting, perhaps an essential oil) would show whether this patient, as seems probable, is peculiarly sensitive to formalin vapour.

INCOME TAX.

Cash Receipts Paid to Outgoing Partner

"G. O. C." joined a firm on January 1st 1927, taking over the share of an outgoing partner. The firm's liability for income tax is based on cash receipts and payments. "G. O. C." shares of the tax, therefore, is affected by the amount of the debts collected and handed over, not to himself, but to his predecessor. Is this correct?

. Yes. The one to the puzzle is that "G. O. C." is liable in respect of his share of the fees earned by the firm whether they are received or outstanding. Theoretically the firm's liability should be based on gross bookings, less an allowance estimated to cover losses by non-payment. Presumably, in the long run, that basis would yield the same result as taking the cash receipts, and as the amount of the latter is easily calculated and does not involve any arbitrary estimate, it is clearly preferable. The tax that "G. O. C." paid for 1927-28 he paid for the earnings of that year, not for the cash received, and if he had

left the partnership subsequent receipts would simply have represented the gathering in of income on which he had paid tax. That, of course, is the present position of his predecessor. "G. O. C.'s" accountant's reference to business profits is not understood, such profits are seldom, if ever, calculated on any basis but that of the book debts.

LETTERS, NOTES, ETC.

ABNORMAL PIGMENTATION OF THE SCALP

DR. F. PARKES WEBER (London, W.1) writes. With reference to the note by Dr. E. A. Cockayne, on September 29th (p. 592), I would suggest that the rare "black locks" of the hairy scalp to which he alludes are to be regarded as etiotically analogous to simple pigment naevi of the skin of any part of the body, whereas the "white locks" of the hairy scalp (in regard to which Dr. Cockayne refers to the well known Whitelocke family tradition) are strictly analogous to simple achromic naevi of any part. In fact, they constitute a form of congenital local albinism. But without knowing the exact history of any particular case of "white locks" the difficulty is to be sure that they are not of the kind that often follow patches of alopecia areata. Moreover, patches of white hair on the head (and sometimes patches of alopecia areata) may be associated with, and in fact constitute a part of the syndrome of, ordinary vitiligo which is the commonest cause of leucodermic patches in general.

TREATMENT OF CANCER BY INJECTIONS OF PERITONEAL FLUID

DR. SIDNEY FERN (Melbourne, Australia) writes. In your issue of July 14th (p. 86) I referred to a man with malignant disease of the stomach who had been receiving injections of desferriated blood subjected to irradiation by the ultra violet rays. His treatment started on March 22nd, and my note on June 28th was, "Is eating minced lamb, liver and bacon, minced chicken. Does not appear so knocked out as he was. For the last two weeks for some reason his prostate enlarged and caused the use of a catheter." Two x-ray applications caused the subsidence of this in a few weeks enabling him to masturbate freely. About this time an enlarged gland appeared in the right groin, though at first quite soft and not suggestive of malignancy, yet by the middle of August this was decidedly hard and obviously malignant, and at the same time in August a small secondary growth appeared in the abdominal ear. From the middle of June the weight gradually began to decline and more difficulty was experienced in taking food and retaining it, till the middle of August, when it was soon evident that the stomach had practically closed up, and nothing was retained, even fluids being returned as soon as swallowed. At the present time he is slowly starving to death but is being kept free of pain and discomfort as far as possible. In another case of exactly the same type similar treatment has been given, the patient while gaining ground for some time has developed oedema of legs and ascites although still able to take a fair amount of food. Two other cases not malignant had down and out, without any definite disease being detected, have been receiving similar injections, and have gained weight considerably. My own observations are such that I feel that somebody with the available time at his disposal should try out the results of different dosage—dose of irradiated blood or peritoneal fluid, time of exposure to light distance of lamp and concentration by lens. It is also necessary to find out by experiment if milk or other food subjected to the rays will produce the same effects. We are dealing with powerful rays, and until we know these facts we cannot hope to get satisfactory results.

MEDICAL PRAYER UNION

IN reply to an inquiry by "M. B.," the honorary secretary, Dr. Tom Jays Livingstone College, Leyton E.10, writes. The Medical Prayer Union arranges for meetings occasionally in the homes of members in the central part of London and organizes two medical missionary breakfasts each year, one specially for medical students in London in May and the other at the meeting of the British Medical Association in July.

MEDICAL PERIODICALS.

A MEMBER tells us that he has sets of bound volumes of medical periodicals which he would be willing to present to a library if the cost of carriage is paid by the recipient. The sets are, *British Medical Journal*, 1883 to 1900, *Lancet* 1895 to 1903, *Clinical Journal*, 1892 to 1900. The volumes are all in good condition.

A CORRECTION

The address of the Registrar of the National University of Ireland is 49, Merrion Square Dublin, C.17 and not as given in our Educational Number on September 1st (p. 390).

VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals will be found at pages 47, 48, 49, 52, 53, and 54 of our advertisement columns and advertisements as to partnerships assistantships and locumtenencies at pages 50 and 51.

A short summary of vacant posts notified in the advertisement columns appears in the *Supplement* at page 155.

An Address

BY

VOLKMANN'S ISCHAEMIC CONTRACTURE, WITH SPECIAL REFERENCE TO TREATMENT*

BY

SIR ROBERT JOYNS, Bt, KBF, FRCS,
Consulting Surgeon Royal Southern Hospital Liverpool Director
of Orthopaedics St Thomas's Hospital, London etc

I wrote a short paper on Volkmann's ischaemic palsy in 1908, basing my conclusions on cases which I had either treated or with which I had come in contact. Since then, I have met with a sufficiently large number to know that only a small proportion of cases seen are published. This is probably due to the fact that there is thought to be a stigma attached to the practitioner who is involved in the treatment of such a case. One must, of course, recognize the potential dangers in injuries and fractures about the elbow, but it cannot be too emphatically stated that despite every precaution ischaemic contractures may occur.

Volkmann, in 1875, described a severe contracture of the hand which he ascribed to tight bandaging in the treatment of fractures about the elbow, and he said that the deformity was due to a contracture myositis, and not to a primary nerve pressure palsy. He recognized that the condition was very grave and that amputation might be needed. In a classical article, which he published in 1881, he reaffirmed his belief in the ischaemic origin of the affection, which he thought due to deprivation of arterial blood and to venous obstruction, consequently, the muscle perished from want of oxygen and the phenomenon identical with that of rigor mortis set in. He called attention to the important fact that in this condition paralysis and contraction occurred simultaneously, whereas in primary nerve lesions contractions followed later. Volkmann submitted that similar contractions have been known to follow blood stasis due to compression with an elastic bandage, to injuries of large vessels, and from exposure to extreme cold. He spoke of forcible extension of the fingers as likely to produce fracture of bones and tendons. The contributions of Volkmann and Lessa are very complete, and have required but little revision or addition for fifty years.

The pathological changes found in the muscles have been described by several writers. The consensus of opinion is that the essential changes involve degeneration of the muscles and an increase of connective tissue in their substance. In many portions there is absence of sarcolemma nuclei and but few individual muscle fibres. There is round-celled infiltration, showing the presence of inflammatory changes. Transverse striation is absent. Powers, describing the findings in his case says "All superficial muscles of the hand are markedly degenerated, pale, translucent, brownish yellow. The muscle pieces removed from various areas show a varying amount of connective tissue which is fully developed, with few vessels, in every way corresponding to scar tissue. The muscle fibres are everywhere degenerated. The fibres are shrunken of wavy outline, and for the most part are devoid of cross striation. They are frequently broken in coarse granules. In the area where the connective tissue is least advanced the muscle fibres are similarly more normal in striation, the cross striation being at times intact. The tissue taken from the ulnar side shows in general a more advanced degeneration."

Greenfield, reporting on a case of Bristow's, concludes "The whole process seemed to be one of absorption and

replacement of dead muscular tissue by fibrous tissue—the muscle acting as a non-septic, non-irritating foreign body, and being treated as such by the surrounding tissues."

DEFINITIONS AND SYMPTOMS

Ischaemic contraction is a deformity found mainly in children between 1 and 14 years, the majority between 6 and 11. It follows injury to the elbow, and is due to pressure from within or without, or both. It is usually, but not always, accompanied by fracture. In a typical case the wrist-joint is palmar flexed, the carpo-metacarpal bones are dorsiflexed, the interphalangeals are flexed, the hand is often pronated, and the elbow-joint flexed. As a rule, sensation is normal in the milder case, and the electric reactions are unaltered, on flexing the wrist the fingers can be straightened. There is a loss of temperature in the hand and arm, the skin is blue and sometimes blistered, and scars are frequently present. The muscles rapidly waste, and become hard and ropey. If the nerves are sufficiently involved conduction may be lost, wholly or partially.

Symptoms may begin in the space of a few hours after injury. The fingers become numb and swollen, and possess little or no power of voluntary movement. The damage is very often completed in forty-eight hours, so that initial symptoms are very urgent. This point will be dealt with later. Muscular rigidity, and sometimes intense pain, come on early, and then the contracture. After some days the swelling disappears and the altered muscles become hard and resistant. The deformity, if untreated, increases, especially the flexion of the fingers due to the further contraction of the fibrous muscle, and also to the disproportional growth of bone.

There are conditions, however, not often referred to, when the ischaemia is mild and sometimes wholly disappears. I have often seen children who come to me many months, sometimes years, after elbow injuries, who are unable fully to extend the fingers, and yet they can move them with freedom and precision within the range permitted. These cases presented no unusual symptoms suggestive of ischaemia during the initial treatment. Sometimes only two or three fingers are affected, suggesting a very localized muscular lesion. Their condition had remained stationary and the defects were not observed by the parents for some time after active treatment had ended and were then regarded as the inevitable result of a bad fracture. I have met such a condition in an adult who told me that he had never been able fully to extend his fingers since he had had a fracture of the lower end of the humerus when a boy. The contraction only appeared when the wrist was dorsiflexed. Such cases, and we can all recall them, point to the likelihood that ischaemia may occur to a slight degree much more often than is thought. Often we have heard practitioners say that shortly after they had applied splints to the elbow the fingers were blue and swollen, but improved when pressure was relieved.

Brooks, in a series of experiments on the etiology of ischaemic palsy, found that after the obstruction of an artery for several hours, and the subsequent removal of the obstruction, the pulse might return in the artery and all the major branches, and yet the circulation might not be re-established in large areas of tissue. If the arterial obstruction lasted for many hours the muscle might become wholly or in part necrosed, in spite of the resumption of pulsation in all the larger arteries. This pathological change in the muscles was accompanied by oedema, haemorrhage, and by a slow inflammatory reaction but there was not a rapidly developing fibrosis and contracture of the muscles. If the vein was obstructed the artery being preserved, typical ischaemic symptoms followed—haemorrhage, oedema, degeneration, inflammation, fibrosis, and contracture.

These findings support the contention that the haematoma found within the limits of the antecubital fossa in supra-condylar fractures is capable of producing a venous block quite apart from bony displacement, special position of the elbow, or the application of a splint or bandage.

Jepson directed some interesting experiments upon dogs at the Mayo Clinic. In one series he attempted to produce

* The opening paper in a discussion in the Section of Orthopaedics at the Annual Meeting of the British Medical Association Cardiff 1928.

ischaemic contraction by the application of splints, casts, and bandages, but found it only possible to bring about a very temporary deformity.

In a second series of experiments a rubber bandage was applied above the knee of the right pelvic limb, and left on from half an hour to twenty-four hours. The animals which wore the constricting bandage for short periods developed a clawing deformity, but this only lasted from three to four hours. Where the constriction was maintained for twenty-four hours the deformity only lasted for three or four days.

In a final series Jepson operated upon dogs in pairs. In one animal a simple ligation of the femoral vein in Hunter's canal was performed. In the second an incision was made on the medial side of the right thigh, parallel to, and a few inches below, Poupert's ligament. The incision was carried down through the fascia to the muscle, encircling more than one-third of the thigh. The extremity operated upon was cold and bluish in a few minutes. There was no difference in the result of the two operations. The deformity simulated the contracture of Volkmann, and was maintained from six to nine days. When these two operations were combined the results were practically the same.

It was concluded that these experiments were insufficient—without other factors—to produce a true and persistent ischaemia. Accordingly, after the wounds had healed, an Esmarch was applied at the site of operation and maintained there from six to twenty-four hours. Even then the deformity did not persist in all the cases. The animal which wore the bandage longest had a contracted limb for eighteen months. The forefoot and distal phalanges were flexed, while the proximal phalanges were extended, the leg wasted, and became board-like. Jepson, having succeeded in producing a persistent deformity, endeavoured to discover a way of minimizing the effects. A dog on which the incision and ligation had been performed was selected for the experiment. An Esmarch bandage was applied above the knee and left on for eight hours. At the end of this time there was considerable oedema and disturbed circulation. Six hours later the wound was opened and the blood and serum evacuated. Rubber drainage tubes were placed in the intermuscular space and sutured. The swelling began to disappear, and four days later the dog was walking normally. The experiment was several times repeated, each time with controls, and the results demonstrated the important part played by intrinsic pressure in the causation of ischaemia. Their clinical bearing will be referred to later.

The work of Brooks and Jepson is a distinct contribution to the etiology of the subject. Volkmann's contractions are due to a combination of events, the most important of which are obstruction to venous flow, extravasation of blood and serum, and swelling of soft structures causing pressure on vessels and nerves.

Our clinical experience then, supported by experiments, proves the condition to be due to venous obstruction of an acute kind. In my opinion deformity does not occur if obstruction is gradual. Out of the number of cases we see where the veins are pressed upon by growth, callus, etc., how rarely do we find fixed contraction resulting. I have only seen it once, and that was over twenty years ago, as a result of an appalling myositis ossificans, while in this case there was no proof that the ischaemia did not antedate the ossification. Out of scores of cases of myositis ossificans about the elbow I have never seen another case of Volkmann. The oedema gives us our chief clinical proof that the veins more than the arteries are obstructed.

It is, therefore, a direct pressure causing an acute obstruction which is the chief factor in producing a Volkmann. The ischaemia accompanies fracture in about 80 per cent of cases. The tissues are bruised, and considerable effusion of blood and serum may distend the space below the fascia and intermuscular planes. This may be sufficiently great to give rise to cyanosis of the arm, and destruction of the tissue cells, with the formation of blisters. Inflammatory products add to the pressure.

The question of the frequency of peripheral nerve involvement is an important one. J. J. Thomas, in a careful survey of the literature up to 1909, found nerve involve-

ment in 60 per cent of the series. Frank Dixon, in 1926, reports cases where conduction in the median and ulnar nerves was interfered with. Bristow reports a case of Volkmann where the median was completely divided by a sharp projecting end of the diaphysis—the nerve was sutured. Platt gives an instance of injury to the median at two levels. It was impaled on a sharp projecting end of the diaphysis in a supracondylar fracture, and also compressed by intermuscular fibrosis as it passed between the two heads of the pronator radii teres. Hamilton, in 1850, operated on a projecting fragment of bone and found the median stretched over the sharp end of the prominence, and obtained improvement after correction. Other writers have confirmed these experiences.

Although complete loss of conduction is rare, yet it is to be expected that there should be some pressure on nerves—disturbance of sensation in the hand can only occur in this way. The nerves become involved in scar tissue as elsewhere, and doubtless influence the course of the contractions.

CLINICAL CONSIDERATIONS

It is necessary to fix in our minds that this distressing deformity may arise from pressure within the limb or pressure from without. It is generally a combination of both. In view of the penalties which we may have to bear, it should be clearly understood that Volkmann's deformity is not necessarily due to tight bandaging. This offers no excuse for tight bandaging. In no circumstances should bandaging obstruct the venous circulation in the neighbourhood of the elbow, for of all regions this is the most dangerous.

An interesting case was reported recently by Kennon. He was called to see a young woman whose arm was lying on a pillow in extension. The limb was cold, and there was no radial pulse. A supracondylar fracture was found and easily reduced, and the arm treated in the flexed position. A perfect anatomical and functional result followed, but the radial pulse had not appeared eight weeks later.

I have seen several instances in which deformity has arisen where no bandage has been applied. Many years ago, when sailing vessels were common, a man of over 30 years was brought to me with well-marked ischaemic palsy, and a backward displacement of the elbow, the injury having occurred twelve months earlier. He had received no treatment, nor had he used a bandage. I have also seen three cases in children with ischaemia of various degrees who have worn neither splint nor bandage. I have seen two cases, non-traumatic, where tourniquets had been forgotten. In each of these cases there had been distinct ischaemia, with contraction of fingers, in contradistinction to the flaccid paralysis following direct nerve lesions, and they made good recoveries. Ischaemia may follow injuries to the forearm where muscles have been severed and when haemorrhage has been retained. This results in muscle fixation to bone and contraction of the fingers. Similar and more severe contractions follow infections of the forearm.

PROPHYLAXIS

Flexion of the elbow has recently been suspected of causing ischaemia, and it is well to discuss this point. I have always advocated the flexed position of the arm in elbow-joint injuries, especially in supracondylar fractures. I have, however, always endeavoured to reduce the backward displacement of the humerus before flexing. If the arm is merely flexed only very partial reduction takes place, if any. I first extend the arm, supinating and pulling it at the same time. While the thumb is placed on the upper fragment, the extended and stretched elbow should be flexed. This usually, and without difficulty, gives a complete reduction, which can be verified by the screen. I believe, although hardly any reference is ever made to it except by way of denial, that a sharp, projecting upper fragment often adds to the internal venous obstruction, just as it puts pressure on the ulnar and median nerves. This is what occurred in the unrednecked dislocation of the elbow to which I have referred, and those of you

who have dealt with recent dislocations at the elbow will sometimes have met with swollen arm and fingers—symptoms which soon disappear when reduction is effected. If there should be a lateral displacement of the elbow it must be corrected before the arm is flexed. It is not accurate to state that the reduction is as easy if postponed for days. It is often quite impossible to effect reduction then except by operation. When the arm is flexed it should not be in any way forced, and the wrist can be slung under the chin, or a little lower. One must recognize the truth of the observation of Hoy Groves that *very acute flexion* does affect the radial pulse. If the elbow is greatly swollen it would be wrong to flex the arm acutely. Whether there be swelling or not it is a mistake, when the elbow is flexed, to bandage arm to forearm, or the elbow to the side. It is possible to exceed the margin of safety, and of this we should be aware. To make a routine of leaving every case of dislocated elbow, or fractured epiphysis, unreduced for twenty-four hours or for forty-eight hours in order to avoid ischaemia is not reasonable. This advice, if followed, would not prevent, but add, to the frequency of ischaemia, if only from the pressure of bone as in Kennon's case. By far the majority of contractions I have seen have followed the use of the internal angular splint. I have met with one case which had been treated in full extension with a Thomas ring splint, and the bars prevented anything approaching circular constriction. That flexion is safe, if intelligently done, is suggested by the fact that I have never met with an ischaemia in my own practice. The full flexion of an elbow in an unreduced fracture may, I repeat, be hazardous, it requires force which should never be applied. Indeed, the flexion treatment of fractures about the elbow should never require any force in reduction, if the arm does not flex easily, it is suggestive of locking due to displaced fragments. If a surgeon cannot satisfy himself as to reduction by manipulation, the question of operation has to be urgently considered. Limitation to pronation, supination, flexion, and extension immediately after attempted reduction is suggestive of failure. The treatment of elbow fractures by flexion after reduction has so many advantages that it must continue to be the position of choice. Whatever happens, we must never subject fractures and displacements about the elbow to plaster-of-Paris, splints, or bandages. Prophylactic measures demand, therefore, that we should

- (a) Avoid circular compression
- (b) Reduce dislocations and displaced bones
- (c) Avoid all kinds of splints more especially if there is much swelling
- (d) Use no force in flexing the elbow
- (e) Critically watch all cases of fracture about the elbow for the first few days. The warning symptoms are great pain (not always present) stiffening and swelling, cyanosis and lividity of the fingers. Ischaemia may result without obliteration of the radial pulse, but this symptom is at least evidence of pressure. Loss of voluntary movements is a serious omen.

WHAT SHOULD BE DONE IF ISCHAEMIA HAS STARTED

The arm should be released from all restraint which involves compression, and should be elevated. Manipulation of every kind for the further reduction of displacement should be avoided. Murphy, in 1914, suggested if cyanosis continued while the forearm was extended and elevated that a subcutaneous division should be made on the antero-ulnar side of the forearm. The experiments of Jepson, which I have described, supply an argument in favour of Murphy's suggestion. Personally, I have had no experience of the procedure. If the operation is done it should be done early, and rarely later than thirty-six hours after the onset. I can find but little evidence of the results of this operation to evacuate blood and serum. In an editorial note to the thirty-first report of *Progress in Orthopaedic Surgery*, it is stated "Some of us have encountered cases in which ischaemic myositis was present when the patient was first seen, and before any dressing had been applied for the fracture. Contrary to the experimental evidence, which is in favour of venous congestion as the causative factor, the finding in these cases was absent radial pulsation, pallor, and coldness of the hand,

together with inability to move the fingers. The first two developed typical ischaemic contractures. In the third case multiple incisions were made at the elbow and part of the subfascial haematoma evacuated with the result that the ischaemia disappeared and the hand remained normal." I agree with the writers that each a case is very encouraging, and the method deserves further trial.

PROGNOSIS

In my experience the prognosis is always grave, although the function of the hand can generally be improved, sometimes very considerably. I have never met with perfect function in any hand where the symptoms of ischaemia were pronounced. The prognosis is most grave where

- (a) The nerve damage is excessive or complete
- (b) The obstruction to circulation in the fingers has remained pronounced
- (c) The wrist is fully flexed and the forearm is fixed in extreme pronation and there is very limited movement in the elbow joint
- (d) Only *mass* movement occurs in the fingers

The prognosis is more favourable

- (a) When the circulation is good and nerve involvement is not too pronounced
- (b) When the forearm moves fairly freely on the humerus and some supination is possible
- (c) When flexion of the wrist is not extreme and some separate voluntary movements can be obtained in the fingers

The prognosis is very favourable where only a slight contraction appears in the fingers when the wrist is dorsiflexed. This is the unrecognized group where symptoms have only been noticed after the completion of treatment, and are even looked upon as mere stiffness.

TREATMENT

We have dealt with the measures to be taken during the acute stage—a stage which lasts for about a week. Usually the surgeon sees the case some weeks or months later, when the deformities are fully developed. He will then have to decide whether his attack should be a mechanical or an operative one, or a combination of both. Whatever method be adopted, the aim should be to keep the forearm supinated.

Mechanical Treatment

The treatment I advocated in 1908 consisted in gradually extending, first the fingers, then the metacarpophalangeals, and then the wrist. As we know, when the wrist is completely flexed the contractions of the fingers are all lessened, and if they cannot be fully extended this may further be brought about by completely flexing the metacarpophalangeals. When the fingers are straight splints are applied to them, and are used to extend the metacarpophalangeal range. A splint is then applied reaching from the finger-tips to the wrist-joint, and full extension of the hand is secured. This splint is then used as a lever slowly to dorsiflex the wrist, and later a splint is applied from the finger-tips to the elbow, in order to maintain and gradually to increase dorsiflexion. These splints should be taken off every day, or every few days, for physiotherapy. By these methods, which require patience and the help of a skilful nurse, the hand improves greatly in function, the circulation is better, and the fingers are under better voluntary control. All through the years I have made this the routine treatment, and I have usually only operated to secure amputation of the forearm. My conservatism needs no apology, for I have sometimes been called upon to treat cases which have been submitted to operation, and which have improved after this method of gradual stretching. If the ischaemia is complete, and no muscular fibres remain, it is obvious no functional result can be secured, but even then patients are grateful to be cured of the clawed fingers, which have a very depressing effect upon them. Physiotherapy has an assured position in Volkmann's paralysis, as soon as the acute and painful stage is passed. This should consist of radiant heat, contrast bathing, oil stupes, and gentle massage. Electrical stimulation of the muscles should also be prescribed.

Operation

When a nerve is divided it is imperative to operate, even if only sensation results. If I decided to operate upon the median or ulnar (the post-interosseous is rarely involved) I should correct as much of the deformity as possible first of all. I have had so little experience of either the shortening of bones or tenoplasty in this condition that I shall be very interested to hear experiences to day. I have only operated on one case by tenoplasty, shortly after Littlewood recommended it, and the result was not very encouraging. It was an extremely difficult case, and the tendons were very adherent. In a case where I removed a piece of radius and ulna I was unfortunate enough not to obtain union.

A comparatively simple method of overcoming the contraction of tendons was referred to by Max Page and performed with success by Platt. It consisted of detaching the origins of the flexor groups from the region of the internal epicondyle and upper ends of the radius and ulna. I have not had any experience of this operation, but it appeals to me as being sound in conception. It is best performed where, after a period of graduated stretching, a residual contraction remains. In the case I referred to, where a Volkmann's contraction followed an old dislocated elbow, I made a free excision of the joint, and the contraction of the fingers was very much improved. This should only be done if the flexors of the elbow are working.

In cases of tenoplasty the after-care is very important, and the patient should be under constant observation. The arm should be elevated, the splint being applied to the dorsal aspect of the limb. Voluntary movement should be encouraged about the tenth day.

Resection of portions of the radius and ulna was advocated by Garré in 1895, and has been practised by several surgeons. Results are not very encouraging. Tenoplasty and bone resection in combination have been reported. It is well to warn surgeons who have had no experience of tendon work that conjoint operations of this kind in Volkmann contraction are very difficult, and require great neatness and patience, in the case of children they may be prolonged, and for that reason may be accompanied by considerable shock.

Myotomy and tenotomy are not to be recommended, in spite of reports which have been published. The most that can be said in their favour is that they may shorten the time necessary to correct flexion. I would emphasize that the success or failure of any treatment depends on the condition of the muscle fibres and the nerve involvement. If the muscles have been transformed into fibrous tissue no functional result is possible, and the most that can be expected is an improvement in appearance. All statements to the contrary should be doubted.

Where contraction of tendons and fixation of the forearm in pronation, together with very limited flexion, is found, I think a free excision of the elbow-joint, to which I have already alluded, may be indicated. If, in addition to this, the flexor muscle attachments to radius and ulna are detached improvement might be hopefully expected. Before any operation on bone is performed the treatment would be facilitated by obtaining as much correction as possible by gradual stretching.

It is perhaps encouraging to know that I have seen several old cases—some of which have been well treated and others badly—years after all treatment has ended, and the patients have told me that their fingers are more pliable and their hands much more useful than they were. The circulation always improves as the months and years pass, and, unless the destruction of the muscles, or the paralysis, is complete, time is always a favourable factor.

My advice to young surgeons and practitioners who meet with fractures about the elbow is that they must insist upon obtaining an x-ray photograph. If the parents refuse, the refusal should be made in writing. The parents should be told that two serious conditions are apt to follow injuries to the elbow. One is the condition we are now discussing, and which often comes in the first few hours, and the other is myositis ossificans, which is not likely to follow in less than three or four weeks. My further advice is that they should join the Medical Defence Union, for the law may be invoked whatever we may do.

ULTRA-VIOLET RAYS AND THE GENERAL PUBLIC *

BY

W. E. DIXON, M.A., M.D., F.R.S.
(Pharmacological Laboratory, University of Cambridge)

THE NATURE OF RADIATION

ALL matter of the material universe is built of atoms. The atoms are composed of electric units, positive and negative, the various chemical atoms differ from one another only in the number and arrangement of these electric particles. But matter is always associated with a third thing—namely, radiation. Radiation is described as consisting of waves in an all pervading medium, the ether, which is responsible for gravitation, electric attraction, and cohesion, it is the connecting link between matter and ether and is the process by which energy is propagated through space.

Radiation is due to sudden changes or rearrangements in the movements of the constituent electric units of the atom. Any vigorous treatment of an atom may cause new radiations. If electric particles are thrown on to a surface in a vacuum tube radiation occurs, and the so-called x rays are produced. The nature of the ultimate constitution of matter has been determined entirely by a study of these radiations, which are emitted by all substances above absolute zero.

There is another kind of radiation which is emitted by radio active substances. Radium salts emit not only ether radiations, but electrical particles also. These particles (alpha rays) are expelled at a velocity of 10,000 miles per second, and possess so much energy that when they strike a zinc sulphide crystal a flash is seen.

The different radiations can be separated in several ways. A very few of them are appreciated by the retina, and small differences in wave-length or frequency of vibration are responsible for the appreciation of colour.

When radiations pass through a partly transparent object such as a glass prism, the direction of their movement is changed, they become bent in different degrees, according to the various wave-lengths, and can thus be sorted. This is termed a spectrum. All these waves affect one or other chemical substance and can therefore be photographed. If all kinds of rays are present, as in sunshine, the spectrum is continuous, if some are missing the spectrum shows bright lines, and if a continuous spectrum is passed through a substance which absorbs certain rays the ultimate spectrum will exhibit dark lines (absorption spectrum). Other methods may be used to separate out certain waves, as by means of screens.

Animal life has developed and adapted itself to existing conditions—to the plant life which preceded it and on which it was dependent for food, to the atmosphere, and to the radiations around it. Its food was composed of whatever constituents were available from plants—such as sugars, proteins, fats, and vitamins, and its radiations by those furnished by the sun and temperature of the environment. Being developed according to these environmental conditions, the conditions became essential for individual well-being.

The later phases of science have enabled us to analyse these conditions and to modify the foods and radiations which normally obtain. It may be that all this is to the good, that as man congregated in herds, he changed the conditions under which he had developed—as, for example, if he lived in confined areas and ate preserved foods which had lost some of their fundamental properties. This may not be unconnected with the modern craze for vitamins and radiations. Moreover, there is evidence to suggest that these modifications of foods, and unnatural radiation confined to a very limited wave-length, may exert an unfavourable action in certain cases.

The range of electro-magnetic waves extends, so far as they have been mapped, through sixty-two octaves. Visible sun rays occupy only one octave, and all move at a uniform

* A paper read in opening a discussion in the Section of Radiology and Physio-therapeutics of the Annual Meeting of the British Medical Association, Cardiff, 1928.

velocity of 30 000 million centimetres per second Beyond the violet rays of visible light are five octaves of ultra-violet rays becoming progressively shorter in wave-length, solar radiation contains a few of these, something less than an octave On the other side of the solar spectrum are the infra-red waves, about seven octaves, of which solar radiation contains three or four

Sun rays have been used in the treatment of disease for long ages, but during the last thirty years precise observations have been made of their action in disease The proof is complete that they exert a curative effect in cases of surgical tuberculosis, rickets, and in some cases of nerve disease, anaemia, and skin disease Atmospheric conditions alter the action of sunshine to some extent Thus the presence of water vapour acts in much the same way as a fire screen, which lets us see the fire, but cuts out the heat The atmosphere tends to absorb the short wave ultra-violet rays, so that these are likely to be more plentiful in mountainous districts than at sea level The morning and evening sunlight are not so useful as that at midday, since the rays have to travel through a greater thickness of atmosphere Nevertheless light treatment may be practised almost anywhere Swiss doctors assert that mountainous districts give the best results on account of the atmosphere being clean and dry and the rays more intense in chemical properties and ultra-violet On the other hand, doctors in the lowlands claim beneficial results almost, if not quite, as good as those in the Alpine institutions—for example, in the neighbourhood of Berlin It is still a matter of dispute which rays are responsible for the beneficial action and how they act

CURATIVE RAYS

It is generally believed that it is the violet and longer ultra-violet rays that are most important, because these are especially prevalent in the sunshine of mountainous districts and near the sea, where they become refracted and reflected by the sand and water If the short ultra-violet rays were the most important, then the mercury vapour lamp, in which they are very rich, ought to be the most effective treatment Rollier, the pioneer of sunshine treatment, regards the light waves as the most important, and abundant pigmentation as a sign that the patient is deriving benefit Others hold the view that the value of heliotherapy is the direct effect of the power of the rays to produce redness of the skin

All skin contains a substance called ergosterol, when this is acted on by ultra-violet rays it is changed chemically, and the changed substance acts as a preventive to, and cure for, rickets So that in this particular instance ultra-violet is all-important Regarding general benefit, however, all we know for certain is that sunshine exerts a curative action in certain diseases, and that this is not due to the action on the diseased part directly, but to an action on the skin, and only indirectly on the disease When ultra-violet rays are employed in treatment wave-lengths are used some of which are foreign to sunshine Sunshine contains some of the longer ultra-violet rays, but the shorter and physiologically more active are lacking

Ultra-violet rays are generated by special plants designed for the purpose These substitutes for the sun are the mercury arc in quartz and the carbon arc burning carbons with mixtures of rare earths The radiations from these sources produce good effects in certain diseases, and these are generally ascribed to the ultra-violet rays, though this has only been proved in a few instances like rickets The spectral distribution of these lamps varies greatly Sunlight at sea-level contains less than 2 per cent ultra-violet rays, but in a water-cooled mercury vapour lamp the ultra-violet rays may rise to nearly 50 per cent Moreover, the spectral quality of this ultra-violet light is different from that of the sun, in that it contains a large proportion of the very short waves

The carbon arc, the iron arc, the tungsten arc, and the mercury vapour lamp all radiate an appreciable amount of chemically active light But the carbon arc is the only source which produces a continuous spectrum like sunshine and irradiates all kinds of light from infra-red to ultra-violet The others show a discontinuous spectrum, only a selection of waves being emitted The carbon arc light

is not only the best substitute for sunshine on technical grounds, but it gives the best results in the treatment of patients

PHYSIOLOGICAL ACTION OF LIGHT

The skin acts, as a partial screen to the different wave-lengths of light Luminous rays can pass through several centimetres of the body, but ultra-violet rays penetrate much less, and all but the very longest are absorbed by the epidermis The infra-red waves also have little power of penetration Within this area of the spectrum penetration varies with the wave-length, being greatest with the red waves of light and least with the short ultra-violet rays Ultra-violet light, therefore, cannot have a direct action on deeper tissues

Sunlight, ultra-violet rays, and infra-red rays all cause the skin to turn red at first, and, if the dose is repeated or prolonged, to become pigmented later If the skin of a man is exposed to a powerful carbon arc the irritant effect, as shown by redness, can be largely screened off by ordinary glass light passes through glass, but ultra-violet rays are held back On the other hand, a plate of quartz glass through which ultra-violet rays pass has no influence in limiting the inflammatory reaction, which may remain for several days and be followed by peeling and pigmentation Ultra-violet rays are largely responsible for the inflammatory reaction, although sunshine is more effective in influencing the extent and duration of pigmentation Pigmentation from lamps is more superficial and transient than that produced by sunshine, it is a natural protection against the treatment, and we do not yet know whether its production is an advantage or a disadvantage to the patient

Apart from its action on the skin, ultra-violet radiation gives a feeling of well-being and vigour Many other effects on metabolism have been ascribed to ultra-violet rays I believe that most of these are not specific, and can be obtained just as well with, say, a mustard plaster

SENSITIVENESS

The skins of patients differ in their reactions towards light as well as to certain skin poisons like the mustard gas of chemical warfare, some skins react excessively to a trifling dose, and others are uninfluenced by large doses The skin may be compared with a photographic plate Normally only the visible blue waves affect the gelatin silver If the plate is treated with a dye stuff such as rose bengal it is sensitized, and the green waves also act upon the plate, and if it is treated with diethyl methyl isocyanide the plate becomes sensitive to the whole visible spectrum

Ergosterol in the skin is activated by ultra-violet rays and acquires an anti-rickets property Ergosterol in food is activated only by the ultra-violet rays and not by sunshine, but by adding sensitizers to the food the same thing happens as with the photographic plate, and ordinary sunshine will now activate the ergosterol

The variations in the response of the skin to light are probably due to the presence of a sensitizer, and in some people with a supersensitive skin we even know its nature But quite apart from this natural sensitiveness, the condition can be acquired The application of powerful ultra-violet rays alters the proteins of the skin, these abnormal proteins are absorbed, and an allergic condition arises in which the skin becomes intolerant to light The condition is strictly analogous to the worker with mustard gas sooner or later all these people become allergic, so that a trace of the gas in the atmosphere causes skin inflammation The importance of a correct dose cannot be over-exaggerated, since burns may lead to light allergy

INJURIOUS EFFECTS

It is sometimes thought that ultra-violet radiations are beneficial for almost any condition and that they can do no harm Much of the literature in the advertisements on lamps leaves the impression that they are a panacea for all disease In reality very many patients are not benefited by this treatment, and some may suffer injury Take one example it has been shown that no comparative diminution in the incidence of respiratory infections was noted in a series of infants treated during the winter for

a period of three months by the radiation of the carbon arc light. Growth during the first six weeks was greater in the irradiated than in the non-irradiated group of infants, but during the second six weeks the growth was less among the irradiated infants. Similar results were obtained using the mercury vapour lamp.

Injurious effects of sunshine are uncommon except perhaps when it is reflected from snow or water, hence it may cause inflammatory burns or even blindness. The radiations from ultra-violet lamps, which emit rays of shorter wave-length than those found in the solar spectrum, when applied to the skin are so foreign to the body as to be comparable with the administration of a poisonous drug, either may be beneficial in a suitable subject, but harmful in an unsuitable.

A common effect of slight overdosing is sleeplessness, restlessness, lassitude, loss of weight, and nausea. Resistance to bacterial infection is said to be lowered by treating too large a surface. The most obvious ill effects are in the nature of burns, the skin becomes hot, red, swollen, and inflamed. In the sensitive these may extend beyond the region exposed. After more intensive radiation purulent exudation may occur. Repeated applications have resulted in chronic lesions, a pre-cancerous form of dermatitis. It should be understood that there is no difference between a sunburn, an ultra-violet burn, and a scald. The skin effects are often associated with severe pains in the eyes and headaches, sometimes lasting for weeks.

The eye is readily affected by strong radiations from arc lamps, molten glass, or light reflected from snow or ice, inflammation of the conjunctiva and cornea result, and the lens, and even the retina, may be affected. Ultra-violet rays coagulate protein, and cataract is a coagulation of the proteins of the lens, improper irradiation may certainly induce this condition. In a recent letter in the *British Medical Journal* a doctor writes that as a result of an unqualified person's light treatment on a patient of his, who had a slowly maturing cataract, the patient's vision was reduced in both eyes to perception and projection of light only. Some authorities regard ultra-violet light as the principal factor in the cause of senile cataract, glass-blower's cataract is the result of continuous illumination in which the whole of the spectrum is probably concerned. These effects on the eye can, of course, be obviated by wearing goggles, though this preventive is sometimes neglected, as is shown by a report in the *South Wales News* for June 14th last of a case in the Cardiff County Court, in which a woman was awarded £50 damages in an undefeated case against the Cardiff Snarby Clinic. The plaintiff said that she had to face strong rays of light from a lamp and that no goggles were given to her until she had faced the light for two and a half to three minutes.

Physicians are generally agreed that radiation by ultra-violet light is contraindicated in highly nervous and neurotic people, they suffer what is called a grave "psycho reaction," and the treatment does harm. Great caution is necessary in all forms of pulmonary consumption and in other quiescent inflammatory conditions, such as appendicitis. In old people with rigid arteries, in all forms of kidney disease, and in some forms of heart disease the patient is made worse. Eczemas and some other skin diseases are often aggravated by the treatment. It may be that contraindications appear only after the first treatment. The daily press reported recently an inquest on a woman of 47 who died after ultra-violet ray treatment. She had severe burns on her back and legs, and duodenal ulcer followed. The doctor said that he had come to the conclusion that death was due to ulceration consequent upon burns set up by a sun-ray apparatus.

Careful examination is therefore necessary prior to treatment if we wish to be sure that ill effects will not follow. I believe that the expert can determine the necessary dosage for his patient without the risk of harmful general or local effects.

Most of the leading authorities on radiology have pointed out the dangers which may follow the improper use of ultra-violet lamps. Many of the lamps emit rays to which man has never before been exposed. The evidence of the

harm they may do is overwhelming. Few of us would dare to have a prescription containing poisons dispensed by an untrained person, but the dispensers of rays are uncontrolled, unregistered, and may be unqualified.

It is obviously right that the public should be given such information as will enable them to distinguish between those who have been properly educated to dispense rays and others. At the present time all kinds of rays are used by charlatans in Europe and America to impose on the public. Barbers employ them, especially for their lady clients. Beauty institutions have set up baths of blue rays, which are generally harmless frauds, though ultra-violet light has been used. Sun-ray institutes are becoming the fashion, and the public is buying machines and indulging in self-treatment.

Some countries have already taken action. The superior Council of Public Hygiene of France, consulted by the Minister of Works and Hygiene, has declared as follows: "That given the serious accidents which may result from the use of ultra-violet irradiations handled by incompetent persons, it is necessary, in the interest of public health, to confine the use of these procedures to hospital services and to authorize their application only by specialist physicians." In the United States the Council of Physical Therapy has reported on the dangers to the public of self-treatment by the sale of generators of ultra-violet energy. It points out that those not familiar with the possibilities of such apparatus place undue confidence in the advertising literature, unsuitable cases are treated or cases not amenable to treatment. The council regards such sales to the public as detrimental to the public welfare and an encouragement for the sale of worthless generators, since the public has no means of determining the quality of radiant energy.

I have endeavoured to show that treatment by radiation may be either beneficial or harmful, that its employment by unskilled people may cause serious ill effects to the patient, and I suggest that the time has come when some sort of protection must be extended to the public.

ULTRA-VIOLET LIGHT AND THE PUBLIC *

BY

C. B. HEALD, C.B.E., M.D. CAMB., M.R.C.P. LOND.,
Physician to the Electro-therapeutic Department, Royal Free
Hospital, Consultant in Electro-therapeutics, Royal
Air Force Medical Service.

PROFESSOR DIXON has put before you, with the clarity that has helped to make him one of the most popular lecturers in Cambridge, the position of ultra-violet light treatment as it is to-day. It was the extraordinary value of this form of treatment when properly employed, and the potent dangers associated with ignorant use, that led the British Medical Association to form a special subcommittee. This subcommittee was charged with the duty of considering how best the uses might be safeguarded and the abuses abolished.

The report of this subcommittee was considered in turn by the Science Committee and by the Council of the Association, who formulated a recommendation for presentation to the Representative Body. The final form of this recommendation as passed by the Representative Body is as follows:

That in view of the risks to the public involved in the use of electricity and radiation as methods of treatment by untrained and unqualified persons it is to be desired (1) that suitable courses of training should be organized under medical direction for persons who wish to administer this form of treatment, (2) that persons who have satisfactorily followed such a course should be entitled to have their names entered on an approved Roll, (3) that one of the conditions attached to admission to and maintenance on the approved Roll should be abstention from the treatment of any patient except on the responsibility and under the general supervision of a registered medical practitioner, and (4) that patients who require electrical or radiation treatment should be referred only to those persons whose names are on the approved Roll.

* Read in a discussion in the Section of Radiology and Physio-therapeutics of the Annual Meeting of the British Medical Association, Cardiff, 1923.

HARM BY ELECTRICAL TREATMENTS

The first question of all in considering the subject is Can electrical treatments do harm? There is ample evidence that they can

1. Electric Current

Electricity in its simplest form—that is, plain electrical shock—can kill or permanently injure in much lower voltages than those in general therapeutic use. The literature contains innumerable instances of death resulting from currents of 110 volts and under especially when the resistance of the subject was lowered by moisture. This in itself constitutes a formidable danger when electric currents are being handled by relatively ignorant and irresponsible persons. The direct current, one modification of which is known as ionization, is in common use in "therapeutic" establishments, and a number of fatalities have occurred where insulation has broken down or where the apparatus, as connected to the existing mains, has been a permanent and potent source of danger.

The alternating or sinusoidal current and its modifications have caused many fatal accidents, usually when administered in the region of a debilitated heart. I may illustrate my point by reference to a recent curious fatality. The majority here will doubtless remember the death of a lady who had a pair of wireless head-phones on, and reached up to turn off a hand lamp. It came out in the evidence that minor shocks had been received from the hand lamp on previous occasions, also that this was known to at least one member of the household who was in the habit of administering electrical treatments. Training such as is recommended by the Representative Body would have made a fatality of this nature in that particular household impossible.

2. X Rays

I am not going to spend your time by describing to you in detail the dangers of ignorant applications of radium and x rays. They are far too well known. Sir Humphry Rolleston has treated the subject fully in the Mackenzie Davidson Lecture of 1927.¹ The literature abounds in references to injuries resulting from even the most skilled and cautious applications of radium and x rays. Dr Heim Lassen,² in analysing 183 cases of injury from x rays, found that an appalling proportion were due to carelessness and ignorance. Of six plain electrical accidents, two were caused by carelessness and three by ignorance. Twenty-eight patients were burnt under treatment, even though the technique was applied correctly, but of seventy-one burns inflicted by incorrect technique, twenty-two were due to careless and thirty-three to ignorant handling of the apparatus. Forty patients were burnt under diagnostic examination, ten through carelessness and twenty-eight through ignorance. These figures cover only the work of qualified persons, they offer a foundation for speculating on the results of an investigation into the use of x rays by the unqualified.

This state of affairs has led to the institution of special courses and diplomas in radiology and electro-therapeutics for medical men, and already in many hospitals the holding of such a diploma is a necessary qualification for the appointment of radiologist.

3. Ultra-violet Light

An argument sometimes advanced is "Control x rays, radium, and obviously dangerous things like that if you like, but surely no one can do much harm with an ultra-violet lamp. At the worst, all that can happen is an uncomfortable sunburn." That idea I most strongly condemn.

Professor Dixon has shown you the dangers of ultra-violet radiation, and public interest demands imperatively that it should only be used by trained and experienced persons. Professor Dixon and I have examined the evidence of damage by ultra-violet light treatment from the contributions of many writers, and our astonishment in surveying the bibliography is that legislative action should not already have been taken in all civilized countries.

Of the list of ailments that have been adversely affected by ultra violet light treatment let me only mention three: quiescent phthisis, chronic nephritis and arterio-sclerosis.

These alone should be sufficient to warn off the unqualified therapist. How is he to determine the presence of quiescent phthisis, chronic nephritis, or arterio-sclerosis? Many of the contraindications to ultra-violet light treatment are such that the fully qualified doctor finds it hard at times to be certain of their presence. There is not the least hope of the unqualified detecting them before damage is done, and yet the attitude of the Ministry of Health is hardly favourable to restrictive legislation, or is one that requires further convincing. The Minister of Health, on May 17th 1926, in answering a question by Colonel Day calling for control of unskilled treatments, said:

I have not received any evidence of injury resulting from the use of ultra violet rays by unqualified persons but if the honourable member is aware of any specific cases in which such injury has arisen I should be glad if he would furnish me with particulars with a view to further inquiry.

4. Diathermy, etc

May I for a moment remind you also that infra-red rays are not free from difficulties and dangers when improperly employed? A medical man reported in the *British Medical Journal* (1927, ii, p 1118) that he had suffered from agonizing pain and syncope with prolonged weakness and loss of sensation after the application of radiant heat to the left leg for twenty minutes at 12 in.

Diathermy, generally considered to be merely a means of heat, is actually a radiation treatment of the tissues manifesting itself as heat after the waves have been absorbed and degraded into heat waves. The dangers of the use of this current are primarily those of technique, causing severe chronic burns, while shock from the primary transformer is also not unknown. A man who was having his chilblains treated was suffering, unknown to the operator, from syringomyelia, which rendered his fingers anaesthetic. The result of his treatment was severe blistering and ulceration. This is a condition which no unqualified therapist can be expected to recognize.

THE CASE FOR A ROLL

Innumerable examples might be cited, but without further elaboration it is clear that the whole field of medical electricity has possibilities of causing temporary or permanent injury, of adversely affecting diseased conditions, and even of causing death. The evidence for the dangers is overwhelming and it is obviously a matter of vital public importance to take the most effective means of preventing them. The words of Sir Alfred Mond when introducing the Dentists Act, 1921, in the House of Commons apply most aptly to the present position of the so-called "medical" electrician. He said:

It is by mere accident that a large uncontrolled, unregistered unqualified service has been allowed to work in this country and that one of the most difficult and important operations on the human being has been allowed to be practised by anybody who sets himself up, without any knowledge of any kind, and that the public have been entirely unprotected against this kind of thing. We are now endeavouring to bring [dentistry] up to a higher standard.

As John Burns said in the discussion in the House on the Midwives Act, 1902:

'If it is necessary to register doctors to educate them and to exalt the standard of their qualifications then surely nurses and midwives ought to be highly trained and registered.'

To his "doctors" we can add to-day "midwives and dental surgeons." Then why not electro-therapists?

Analogy with Chemists

I hear of many patients each year who have been sent by their practitioners to unqualified persons for electrical treatment, without any attempt to control or to specify this treatment. This sort of thing is more or less tantamount to a doctor saying to a patient, "Go to the chemist and get something for your headache," but it is distinctly worse than that, for to-day and for over a century in England we have taken our prescriptions to any dispensing chemist with a tranquil mind. We have no doubt that he will accurately compound that prescription for safe administration to ourselves. We have equally no doubt that on his shelves lies enough of the very remedy we are going to take with benefit to kill us many times over. Our reason for going so trustingly to the chemist is that ever since 1815 chemists have been a trained and registered

class Before the Apothecaries Act, overdosing or harmful compounding was not infrequent Just as morphine in small doses may save a life, and in larger doses take it away, so suitable doses of electrical rays and currents may save, while unsuitable doses may harm or kill Just, therefore, as in 1815 the public demanded protection from the untrustworthy chemist, so now should they demand assurances that those who are exposing their delicate body mechanisms to currents and rays of electricity shall have had adequate training and experience

As Sir William Priestley said in the *British Medical Journal* in 1886 (ii, p 1121)

"In England the principles of liberty are carried so far that men insist on their right to employ quacks if they choose, and on being treated medically even to their own hurt, if it so pleases them The only possible limitation is to insist that the public shall be able to distinguish between those who have been educated and registered and those who have not, and to impose penalties on those who pretend to be registered when they are not so"

On this principle were founded the Medical Acts of 1858, and the Dentists Act of 1878

The formation of a roll or register of persons regarded by a competent authority as suitably qualified to administer medical electricity would enable those of the public who cared for their own safety to be sure of their therapist It would also be of great value to doctors, who would thus be able to select a suitable assistant to whom to send their cases The duly qualified among the medical electricians would welcome it, if for no other reason than that it would protect them from the unfair competition, backed by advertisement, of those who have spent neither time nor money in acquiring skill and experience, and who are not bound by any ethical rule of modesty or truthfulness The advancement of knowledge and scientific research would be forwarded by any central body whose duty it was to examine and certificate workers in this field, and, indeed, permanent and continuous research is impossible without some strong co-ordinated body of intelligent workers

The difficulties and the needs have already been recognized by three associations—the Institute of Radiology, the Chartered Society of Massage and Medical Gymnastics, and the Institute of Blind Massengers These all provide suitable courses of instruction, and impose safeguards and ethical standards These organized bodies are already available, and have only to be provided with the necessary public support and legislation to make their existing registers into one authoritative whole, with the prestige and power of the law behind them Unsupported they can do comparatively little The patterns for such a register, are obviously those of the Central Midwives Board and the Dental Board

The Penal Clause

Distinct from, but closely linked with, the formation of a register is the difficult question of a penal clause—that is to say, legislation forbidding the unregistered to engage in these particular forms of practice This was very acutely debated in the House of Commons on the occasion of the passing of the Midwives Act, 1902 As Mr Heywood Johnston pointed out, with the sole exception of the Apothecaries Act, 1815, the current of legislative authority had up to that time been against penalizing the unqualified practitioner The Medical Act, as we all know, provided a register, ethical supervision, and adequate standard of education The Dentists Act of 1878 did the same thing for dentists, laying down that an unregistered person should not be allowed to use the title of dentist or any title implying that he was specially qualified for dentistry The words "specially qualified" led to a number of cases in court, until finally the decision of the House of Lords in *Bellerby v Heyworth* established that the words imported a professional qualification entitling to registration, and not merely skill or competence This decision was the charter of the unqualified dentist, and there grew up in consequence a situation in the realm of dentistry which bears a striking resemblance to that in the realm of electrotherapy to-day The result was the establishment in 1920 of a Departmental Committee to "investigate the extent and gravity of the evils connected with the practice of dentistry and dental surgery by persons not qualified under the Dentists Act, 1878" That committee sat for twenty-seven days and examined twenty-seven

witnesses, producing a voluminous body of evidence It then spoke with no uncertain voice

'There are a large number of unregistered practitioners of indifferent general education who have set up without any training or instruction whatsoever By means of specious advertising and personal canvassing, they ply their calling to the danger of the public, but with very lucrative results to themselves The evidence is conclusive that it is the least reputable section of an unregistered practitioner that has increased most, and tends to increase This constitutes a menace alike to the public health, the registered dental profession, and the more reputable unregistered practitioners Under the existing law any person, however ignorant, unskilled, untrained, can practise dentistry and inform the public by advertisement and otherwise that he practises The only protection the public has is an action for damages in case of injury or the fear of a possible prosecution for manslaughter in the case of death The persons who have taken up the calling comprise a body of men representing every degree of skill, from the totally uneducated unskilled man to the highly qualified practitioner'

It is impracticable for the general public to know whether they are to be treated by properly qualified persons or not

Every word of this might stand as a description of the position to-day in medical electricity Yet this was the state of affairs forty-two years after the establishment of a register supervised by the General Medical Council, but unsupported by any penal clause It is impossible to avoid the conclusion that valuable time might be saved and terrible damage averted if we took to heart from the start the lesson of the Departmental Committee's findings Unhesitatingly—forty-two years too late—they reported

'We have considered most carefully the different representations which have been made to us, and are of opinion that, in the interests of the public, dental practice by unqualified persons should be prohibited under penalty, and that nothing short of this is likely to prove efficient We are further of opinion that the most satisfactory way of distinguishing a qualified from an unqualified person is by the formation of a register of qualified persons Unqualified persons should not be permitted to hold themselves out as willing to practise dentistry or perform dental operations'

The opponents of the penal clause in the Midwives Act held that it would be contrary to the general principles of English justice, that it would create a new offence, and that it would constitute a monopoly Those in favour of the penal clause pointed out (see Hansard, vols 103 and 109) that the omission of that clause would make the bill ineoperative, futile, and to a certain extent mischievous, that it was a matter of common knowledge that there were a considerable number of unqualified women who constituted a serious danger to the public, and that a bill which did not suppress the evils out of which the movement for registration had grown would only result in the increase of the irregular, incompetent, and dangerous practitioner

Sir John Tuke argued that it did not create a new offence, but merely extended an existing principle of law to a dangerous class of people, and that the principle had already been applied to chemists, solicitors, and auctioneers, with the object of excluding undesirable persons Mr Griffith Boscawen maintained that unless the ignorant persons from whom dangers arose were prohibited from practising in the future, the worse class would go on as before, and a great deal more harm than good would be done by the establishment of a register The *Medical Register*, as Sir W Foster pointed out, had not stopped the unqualified practitioner one, nor had it caused the public to seek advice exclusively or even increasingly from bone-setters and quacks In the end the penal clause was inserted in the bill

When to these views is added the actual experience of the working of the Dentists Act, with and without a penal clause, the argument seems unanswerable

SUMMARY

If the unqualified, unregistered chemist, dentist, and midwife is to be forbidden by law, then the unqualified electrotherapist, who certainly handles therapeutic measures as dangerous as those of any chemist's shop, and performs operations as delicate and difficult as those of any midwife or dentist, ought to be put in the same position

THE DIAGNOSIS AND TREATMENT OF STERILITY *

BY

ARTHUR E. GILES, M.D., B.Sc. Lond.,

F.R.C.S. Ed. M.R.C.P. Lond.

Consulting Surgeon to the Chelsea Hospital for Women

THE subject of sterility is too often thought of as one that concerns only the woman partner. The man is, in fact, at fault in a large proportion of cases. This aspect is to be dealt with in a later paper, so I need not enlarge upon it.

I. DIAGNOSIS

The correct diagnosis of sterility in women depends on a thorough and systematic investigation of the anatomical and physiological features that affect the transit of spermatozoa from the vagina to the Fallopian tube, the possibility of fertilization of the ovum, and the transit of the oosperm, or fertilized ovum, from the ovary to the uterus. The most rational investigation will be in the following order:

1. The General and Sexual Development of the Woman

The general appearance and the development of the breasts and pubic hair will give indications as to sexual maturity. In order that we may regard this as satisfactory we must also find a normal vagina and uterus, and tubes and ovaries not obviously abnormal, and there must be a history of regular menstruation, neither excessive in quantity nor too scanty. If we also elicit the information that coitus is accompanied by normal desire and sensation we may conclude that the ovaries are sufficiently developed and that the endocrine function is normal.

2. The Possibility of Normal Intercourse

There may be a history that intercourse has not been possible, owing to want of virility on the man's part, or because it is too painful for the woman. In the latter case the possibilities that we have to think of and investigate are: First, the existence of actual obstruction, due to absence of the vagina or an imperforate hymen. This will at once be revealed on examination. Secondly, undue narrowness of the vagina due either to anatomical stenosis or to functional spasm of the vaginal muscles (vaginismus). Thirdly, the presence of sores or abrasions at the vaginal orifice, or vulvo-vaginitis, of simple or of gonorrhoeal origin. Fourthly, more deeply seated trouble such as tubo-ovarian inflammation or ovarian prolapse, when pain would be the result of deep pressure. It is to be remembered that the vagina may appear to be normal, yet it may be relatively narrow, and, moreover, painful vaginal spasm may be induced under the excitement of attempted intercourse, though it may not be elicited by a digital examination.

3. The Effectual Reception of Spermatozoa at the Os Externum

This presumes, as the essential factor, that the os externum shall be duly patent. Complete occlusion of the os is rare and causes distension of the uterine cavity by blood (haematometra) when the menstrual function is operative. On the other hand, a wide dilatation of the os is not essential to conception. The normal vaginal os can, it is true, expand to admit a sound, but in the ordinary state the cervical canal is only a potential tube, having its walls in apposition. The typical "piahole os" cannot be expanded without forcible stretching and may be unfavourable to conception, but we cannot say that conception may not occur. I recall a recent case in which a patient after curetting, developed a secondary contraction of the os externum that would not admit even a small probe. As she was anxious to conceive I advised dilatation. She let the matter slide, yet conceived about a year later. I saw her when she was three months pregnant, and the os looked quite normal.

There are two conditions of the uterus that produce a hindrance to conception, the effect being the same in both cases. These are marked retroversion and acute ante-

flexion. In both cases the cervix is turned unduly forward, with the result that during intercourse the cervix is pushed still further forward and the external os is virtually shut off from contact with the semen by being pressed against the anterior vaginal wall.

I am convinced that these conditions play a much more important part than is usually appreciated, and that the *modus operandi* is the one that I have suggested. I pointed it out in my monograph on sterility in discussing displacements. It is certain that the rectification of the position of the cervix has frequently been followed quickly by conception, even after some years of sterile married life.

Under the same heading we can consider and investigate whether the character of the vaginal discharge is such as to be noxious to the vitality of the spermatozoa. When the vaginal secretion is very acid and the organism is not accompanied by a sufficient discharge of neutral or alkaline secretion from the cervix to counteract it the spermatozoa may be enfeebled or destroyed before they have time to gain admission to the cervical canal.

The only certain way of determining whether the semen is making an effectual entrance is to examine microscopically the contents of the cervical canal shortly after intercourse. If live spermatozoa can then be observed we may conclude that the fertilizing process is normal so far.

4. The Passage of Spermatozoa through the Uterus into the Tubes

We may assume that in a healthy uterus the spermatozoa can ascend readily to the uterine ostia of the tubes. There is a simple method of judging the healthiness of the uterus that is often possible. On examining with a speculum, a drop of mucus is often seen at the external os. If it is a clear mucus the endometrium may be assumed to be healthy, or at least non-inflammatory. If the appearance is that of muco-pus it is probable that there is a cervical endometritis.

There is no doubt that conception can occur even when certain pathological states of the uterus are present, such as mild endometritis and fibroids in the uterine wall. I have endeavoured, in previous writings, to show that the relation of fibroids to sterility is that of effect rather than of cause. But a serious endometritis undoubtedly prevents conception by destroying the spermatozoa before they reach the tubal openings, even if they have effected an entrance into the uterus.

As to the passage of spermatozoa from the normal uterus into the tubes, we had to rely formerly on assumption. If uterus and tubes felt normal bimanually we assumed that it was all right, but it is possible for a mild salpingitis to settle down so that no physical signs are evident yet a vital damage may have been done in the form of sealing up the tubal opening into the uterus. We now have a reliable means of determining this point by insufflation of the tubes. The passage of air through the tubal openings can be demonstrated in a threefold manner: by the fall of the pressure gauge, by listening over the lower abdomen with a stethoscope, and by seeing the bubbles of air escaping through the fimbriated end of the tube into the peritoneal cavity by means of an x-ray examination.

5. The Possibility of Fertilization of the Ovum

Here our range of investigation ceases. We have no means of telling whether healthy ova are maturing and are being received into the tube, where fertilization presumably takes place.

6. The Possibility of the Normal Development of the Fertilized Ovum in the Uterus

On this subject also our diagnostic abilities are limited. It is a legitimate assumption that in most cases if there has been no obstacle to impregnation there will be no obstacle in the way of development. But we do not know what are the conditions under which an oosperm will fail to reach the uterus, but will remain and try to grow as an ectopic pregnancy. Nor have we certain knowledge of the conditions under which an oosperm may pass through the stage of nidation, yet fail to develop to full time. We can, however, premise that such a degree of endometritis

* Read in opening a discussion in the Section of Obstetrics and Gynaecology of the Annual Meeting of the British Medical Association, Cardiff, 1928.

may exist as will allow impregnation, but will not allow healthy placentation, so that a miscarriage results.

After this outline of the principles of diagnosis we can consider the broad lines of treatment.

II TREATMENT

It is important first to recognize the conditions in which sterility is incurable. For when this is the case it is much better that the patient and her husband should know and accept the truth than that they should continue in a state of alternating hope and disappointment.

Under-development—There are minor degrees of under-development which, though unfavourable, are not hopeless. An undersized uterus associated with infrequent and scanty menstruation may represent a delayed rather than an arrested development. In such a case the stimulus of marriage is probably the most successful treatment. In addition, the endocrine function may be assisted by the administration of thyroid and ovarian products. Thyroid extract can quite well be given by the mouth, but the same cannot be said of ovarian extract, the properties of which appear to be destroyed in the stomach. It should therefore be given by the hypodermic injection of freshly prepared ovarian substance. The implantation of ovaries by surgical operation has been advocated and practised, but the recorded results are not such as to lead me to recommend the procedure.

Faulty Metabolism—Pronounced obesity appears to be antagonistic to reproductive activity. An analogy is supplied by some lower forms of life in which a phase of nutrition without reproduction is followed by one of reproduction without nutrition. It is certainly a matter of clinical experience that fat sterile women have become fertile when the fat has been reduced. When I am consulted for sterility by a patient who is unduly stout I always advise as a first step the reduction of weight, not so much by the omission of this or that article of diet as by the diminution in the total amount of food taken. This can be supplemented, if necessary, by the administration of thyroid.

Difficulty in Intercourse—A rigid hymen should be incised. Narrowness of the vaginal orifice can usually be remedied by digital dilatation under an anaesthetic. In other cases the orifice can be enlarged by a plastic operation. In cases of dyspareunia the source of the pain should be located and the cause corrected. Vaginismus is sometimes difficult to overcome, but here also a forcible dilatation under anaesthesia may be followed by considerable improvement. It must be remembered that the difficulty may be due to the man. In that case suitable treatment may do a great deal. But if he remains incapable of effecting introduction, and healthy spermatozoa can be demonstrated in the semen, the case is a proper one in which to try artificial insemination.

Hindrance to the Entry of Spermatozoa into the Cervical Canal—When the external os is unduly contracted, or of the "pinhole" type, a dilatation of the cervical canal should be carried out. I should like to utter a warning against doing unnecessary damage. A moderate degree of dilatation is all that is necessary, and incisions of the cervix should be avoided. When the hindrance is the result of marked ante flexion of the cervix the treatment is to carry out a moderate dilatation of the cervical canal, with concomitant straightening of the uterus, and to introduce a glass intrauterine stem pessary, which is left in position for ten or twelve days, during this time the patient must remain in bed. A retroversion or retroflexion must be rectified so that the cervix is in a normal position during intercourse. In the first instance, the uterus can be placed in the normal position by digital manipulation or with the help of the sound, and the effect watched. I have had cases in which this simple procedure has been followed rapidly by conception. If the displacement returns, the possible alternatives are reposition followed by the introduction of a Hodge pessary, and correction of the uterine position by operation. In my opinion the continued wearing of a pessary is in itself unfavourable to conception, owing to the tendency to the setting up of unhealthy and irritating discharge. Consequently I use that only as a temporary measure, and in persistent cases I advise operation.

Noxious Discharges—Apart from gross and serious conditions such as carcinoma, uterine fibroid, and polypus, discharge is due either to adenomatous disease of the vaginal aspect of the cervix (erosion) or to endometritis, especially of the cervical type. The former should be treated by suitable applications made at intervals of a few days. The latter requires curetting. I should like again to emphasize the importance of avoiding unnecessary injury. The cervical canal should not be dilated further than is necessary for the introduction of the curette. The scraping should be done thoroughly, but not too fiercely, and should be followed by swabbing out the uterus with some antiseptic such as tincture of iodine. Strong reagents such as iodized phenol should not be used, lest they produce a too strong cauterizing effect.

Tubal Obstruction—When the tubes are not patent the case is hopeless unless surgical measures are taken for the restoration of patency. For this purpose the abdomen is opened and the condition of the tubes is carefully investigated. In the presence of pyosalpinx and hydrosalpinx the prognosis is bad but not necessarily hopeless. The tubes may be opened and drained, care being taken to ensure that the uterine ostium of the tube is patent, by passing a fine probe. When the fimbriated end of the tube is sealed, but the tube not otherwise too diseased, an artificial ostium is obtained, by making an incision at the outer end of the tube, as much in relation to the ovary as possible, and oversowing the edges. Here again the patency of the uterine ostium must be demonstrated. Lastly, when the fimbriated end of the tube is patent, and the obstruction is obviously at the uterine end, an effort must be made to restore the passage. To accomplish this it may be necessary to open the uterus and pass a needle threaded with catgut through the ostium and along the tube. The catgut is left in position, and the uterus closed again.

Endocrine Inadequacy—Metabolism and endocrine deficiency are now known to play an important part in affecting fertility adversely, probably by depressing the vitality of sex cells in both the man and the woman. Besides the recognizable symptoms of these conditions, important laboratory data are now obtainable by the chemical pathologist, having special reference to the total basal metabolism and to the blood morphology, together with suggestive information derived from a study of the process of excretion. It has been suggested that such laboratory tests should be carried out on both husband and wife as a routine procedure in all cases of sterility. Without endorsing the routine practice I feel sure that in many cases where ordinary examination has failed to show any definite explanation of sterility the laboratory tests may give such information as may lead to a scientific and successful line of treatment.

In conclusion, it may be said that the problem of sterility must be approached with a much broader outlook than was formerly the case, and that patient and detailed investigation followed by the scientific use of the methods of treatment now available, will result in a larger proportion of cures than was formerly thought possible.

DIAGNOSIS AND TREATMENT OF STERILITY IN WOMEN *

BY

SIDNEY FORSDIKE M.D., F.R.C.S.,
Surgeon to the Hospital for Women, Soho Square, W.

In opening a discussion it is necessary to define the limits of the subject under consideration, and as the term "sterility" is used by different writers with reference to (1) a woman who does not bear a living child, and (2) a woman who offers no evidence of being fertilized, I must indicate that I take the second definition to be the true one for the argument in this paper, and I regard sterility as referring to a woman who, living a normal marital life and desirous of having children, yet offers no evidence of being fertilized. The causes of sterility may be broadly divided into (1) congenital causes, (2) acquired (3) functional. From the

A paper read in a discussion in the Section of Obstetrics and Gynaecology of the Annual Meeting of the British Medical Association, Cardiff, 1928.

Amnerian's point of view, however, they are divisible into two groups on physical examination

A Those in which gross lesions are present

B Those in which no gross lesions are present, and no sufficient lesion to stamp it as the cause of the condition

The subject is far too extensive to be dealt with exhaustively, and I intend to limit my argument to the examination and treatment of Group B. The investigation will involve (a) knowledge of the semina, (b) examination of vagina and cervix, (c) investigation of uterus and tubes, (d) investigation of ovaries and pelvic peritoneum

Conditions which are Essential to Fertility

Healthy spermatozoa must be received into a healthy vagina, with a normal cervix, uterus, tubes, and ovaries. It is therefore clear that the initial inquiry must begin with the man, and not only must he manufacture normal spermatozoa, but he must also be capable of conveying them through a normal organ to the vagina. The necessity of this part of the investigation becomes apparent when we consider that 25 per cent of childless marriages are due to the condition of the husband. I have reports upon the semen of 164 men whose wives came under my care for sterility, out of which 46 were found to be defective, and they are divisible into three classes

- | | |
|-----------------------------|------------------------|
| 1. Male absolute sterility | 24 cases=14.6 per cent |
| 2. Male relative sterility | 18 cases=11.0 per cent |
| 3. Male decreased fertility | 4 cases=2.5 per cent |

Group 1 Absolute Sterility—These cases were examined on several occasions after the first negative, but no spermatozoa, living or dead, were ever found

Group 2 Relative Sterility—This group consisted of cases in which a few deformed and broken spermatozoa were occasionally found, together with mucus, pus, and crystals. In some of the cases one or two feeble abnormal forms were found occasionally, but that appeared to be the highest value the semen ever attained on repeated examination. One hesitates to place them in Group 1 so long as a living spermatozoon can be seen, but with full knowledge of the physical condition of the women there is no doubt that these two groups must be added together to arrive at the incidence of sterility in man, and they represent 25 per cent approximately

Group 3 Decreased Fertility—These were cases in which the spermatozoa were very few in number though normal in appearance, and impregnation of a normal woman was possible

Investigation of the Woman who is Normal to Physical Examination

The investigation should commence with the search for spermatozoa in (a) the vagina, (b) the cervix, and when found prove coitus

(a) **Vagina**—In the vagina it is rare to obtain any living spermatozoa, for the examination takes place too long after coitus, and they are very rapidly killed and disappear. I have never succeeded in recovering spermatozoa from the vagina four hours after coitus, whereas with an interval of two hours only they can be found in some of the cases

(b) **Cervix**—Living spermatozoa can be recovered from the cervical canal much more frequently within a few hours of coitus, and when found they show that not only is the man normal but that the vagina and cervix are healthy. In cases where there are none in the cervix and only dead ones in the vagina, the condition of the vagina and cervix needs investigation more especially with regard to the acidity of the secretions. When living spermatozoa are recovered from the cervix then the investigation must be transferred to the uterus, tubes, and ovaries. The possible lines of inquiry are

1. Exploration of the uterus by dilatation of the cervical canal and possibly curettage
2. Inflation of the uterus and tubes by gas or air
3. Investigation of the uterus and tubes by opaque bodies
4. Exploration of the pelvis by laparotomy

1. Exploration of the Uterus by Dilatation of the Cervical Canal

This is probably the commonest procedure adopted, but unless the tubes are patent it is indefensible and may be dangerous and therefore should only be undertaken after the tubes are known to be normal. In the absence of

symptoms and physical signs it tells us nothing, but it is conceded that, as a therapeutic measure, it is followed by pregnancy in a certain number of cases

2. Inflation of Uterus and Tubes by Gas or Air

Inflation of the uterus and tubes was introduced by Rubin in 1919 and has become a diagnostic measure of the first importance. He has since then made use of this procedure as a therapeutic measure, and claims 10 per cent of pregnancies, there is no doubt that it is sometimes followed by conception, but whether in consequence of this interference remains to be discussed

Technique of Inflation—There must be complete absence of any signs of infection of the vagina, cervix, uterus, tubes, and pelvic peritoneum—no tenderness, swelling, or fever. It is of vital importance that it be undertaken at a time when there is no uterine haemorrhage and between the periods, thus avoiding any risk of air embolism, a case of which, fortunately not fatal, I reported in the *Lancet* in December, 1925. It is further most important to exclude any grave cardiac lesion for an unfortunate result might ensue even from passing the uterine tube without the added stress of a pneumoperitoneum, however small. Rubin depends upon a pneumoperitoneum as demonstrated by x-ray investigation of the peritoneum, this is, however, quite unnecessary, as it can be adequately proved by physical signs

Apparatus—A convenient and portable instrument for use is Provis's modification of Currier's apparatus, in which a sparklet of carbon dioxide provides the reservoir of gas, it is connected to a volumeter placed in a jar of water, the jar being connected by one tube to the manometer gauge and by another tube to the uterine end of the uterine tube

Procedure—A day is arranged to fall somewhere between the fifth and tenth day after the termination of the monthly flow. On the two preceding nights the patient uses a glycerin plug which is introduced into the upper end of the vagina overnight and removed in the morning, the object being to soften the cervix. The patient is placed on the table in the lithotomy position, with the table tilted into the Trendelenburg position, in this position the suprapubic area forms the dome of the abdomen, and fluid placed in the vagina will remain there. The cervix and vagina are dried with mops and then thoroughly painted with iodine, a tenaculum fixes the cervix and Nos 1 and 2 dilators are passed, and then the uterine tube, which is of the calibre of dilator No 3 but hollowed through out and terminates in lateral eyes like a male catheter. The objection to the terminal opening is that the end of the instrument might be pressed closely against the uterine wall, and air be forced into the capillaries. A rubber acorn plug is used by some surgeons for the purpose of closing the os, but it must be inefficient as it necessarily tends to open the os wider rather than to seal it up and it is much better to close the cervix around the tube by means of light pressure from forceps of the tenaculum pattern. The gas reservoir is now connected to the uterine tube, the vagina is filled with sterile water, and the gas turned on slowly. The needle in the manometer rises steadily until the gas begins to escape into the peritoneal cavity, when it falls rapidly. The water in the vagina immediately warns us if the gas is flowing back from the uterus and, provided the apparatus has been tested beforehand a falling pressure must indicate patency of the tube or tubes

Tests of Patency

Difference in the percussion note in the suprapubic area before and after inflation

Auscultation over the Fallopian tubes will indicate the bubbles of gas passing through the ostia

Falling pressure in the manometer indicates the flow of gas

Pain in the chest and shoulders after the patient has been in the erect position for a short time indicates pressure of gas on the diaphragm

Anaesthesia is only necessary or advisable in cases where the instruments cannot be passed through the os, and the test can be applied in out-patients and the patients allowed to go home immediately afterwards provided it is properly done. I do not often use more than 40 c.c.m. of gas, the minimal amount passes into the peritoneum and the patients are rarely bothered with any after-effects

The question of the extent of gas pressure to be used is of great importance, and my practice is as follows

Without anaesthesia I utilize a pressure of 300 mm. Hg provided the patient does not complain, and I then know that the tubes are definitely closed if once that pressure is attained and no air passes

With anaesthesia I never go beyond a pressure of 200 mm. Hg, for the patient cannot warn me of tension pain

With anaesthesia and with the abdomen open, so long as I can see what is happening, I allow the pressure to go up to 300 mm Hg, but I always fill the pelvis with normal saline, by which means we can see how far the air penetrates along the tubes and whether any escapes at the fimbriae.

If the test is positive there is no doubt about the patency of the tubes, but if negative, does it mean that the tubes are closed? It may mean that the tubes are temporarily blocked by kinking, as in extreme retroversion of the uterus. I have opened the abdomen of a woman, who was negative to gas at 300 mm Hg and Ipiodol, to find that as soon as the uterus was lifted forwards into anteversion the gas flowed at 120 mm Hg, therefore, with extreme retroversion I always replace the uterus before attempting inflation.

When we have demonstrated the condition of the tubes by inflation we have to consider the next step (a) when the tubes are patent, (b) when they are closed.

With patent tubes and the patient remaining sterile, are we to advise laparotomy for investigation of the ovaries? The answer to this question we will consider when dealing with the injection of opaque bodies.

With closed tubes, are we to advise laparotomy with

FIG 1.—Shows the uterus full of Ipiodol but the tubes are not seen. This result means that the tubes are blocked at the cornual extremity and probably disorganized throughout. I opened the abdomen and found extensive pelvic adhesions with both tubes in a state of hydrosalpinx and the ovaries buried.

a view to some form of plastic operation upon them? If we accept Rubin's views we should not only be able to diagnose whether one or both tubes are closed, but also the site of obstruction from the distribution of the pain during inflation. Those of us who have had a large experience of inflation are not prepared to accept Rubin's claims, and I, while readily acknowledging the advantage of inflation, deny that it affords us any information beyond the patency or closure of the tubes, the site of closure remaining unknown. The diagnosis of the seat of obstruction will not make any difference to those surgeons who claim success from operations upon any part of the tube, whether it be at the cornual extremity (Fig 1) or at the fimbriated end (Fig 2), but my experience compels me to ascertain all I can about the obstruction before I undertake any operation for its relief. I have performed many operations upon the isthmus of the tube, including resection and anastomosis with and without strands of catgut placed in the lumen, implantation of the cut end of the tube into the uterine cavity, and the sliding operation, where the pavilion is anastomosed to the cornual end of the tube. In all these cases before closing the abdomen I have attempted inflation from the uterus in the ordinary way, but in none of them did it succeed despite a pressure of 300 mm of mercury. In some cases the gas escaped at the seat of anastomosis, in others it did not pass at all, and a further attempt, made after the abdominal wound was healed, proved equally abortive. When we remember that the lumen of the isthmus is so small as only to admit a fine probe in normal healthy tubes, it is small wonder that reported successes, after operation upon this part of diseased tubes are received with reserve. For my part, after an extended

experience, I have come to the conclusion that plastic operations upon the narrow part of the tube are not justified.

Obstruction of the tube at the fimbriated extremity (Fig 2) is a very different matter, for here, whatever may happen subsequently, there is no doubt that the tubes after operation are patent at the moment of closing the abdomen, and in a fair number of cases where the operation has been efficiently done they remain open, and in some cases pregnancy has ensued. Even in these cases, however, it is necessary to be guarded in giving an opinion as to the ultimate result, for out of twenty cases eleven were closed again within three months, two were closed within nine months following a history of pelvic inflammation, and seven remained open, two of which became pregnant. We may therefore say that the operation was successful in 45 per cent of cases, but that successful results were only obtained in 10 per cent, and we shall probably agree in describing this as disappointing.

The most favourable cases are those in which the fimbriae can be saved, for this means that there is a minimum of trauma and the least production of raw areas, for the omentum comes down and effectively seals the new opening where fresh surfaces are left exposed. The operative

FIG 2.—Shows uterus and tubes full of Ipiodol. There is characteristic clubbing of the left tube owing to closure of the abdominal ostium. The right tube is prolapsed and also closed. This is the only favourable type for plastic operation.

successes in my cases were nearly all in patients in whom the fimbriae were unfolded and the only incision was into the peritoneum which glued them together. A further essential is that the ovary should be freed and loosely fixed in the mouth of the new ostium. In cases where an incision is necessary to establish a new ostium the serous coat should be undercut so that the suture carries the peritoneal edge over the raw muscular surface, thus preventing the formation of adhesions. On this evidence we are justified in concluding that obstruction of the tubes in the isthmus offers no scope for surgery from the point of view of sterility, but that closure of the fimbriated end offers some chance as the result of operation, therefore it is all important to decide upon the site of obstruction before undertaking any operation.

3 Investigation of Uterus and Tubes by Opaque Bodies

The substance I use, after numerous experiments, is Ipiodol. It is a viscous oily compound of iodine (40 per cent) and oil, and the opacity to x rays is due to the iodine content. It has no ill effect upon the peritoneum, which I have now proved by experiments upon animals, and by extended clinical use. I have opened the abdomen of many patients after the use of Ipiodol, in some cases within a few days and in others after weeks, and I have not found any evidence of a disturbed peritoneum, furthermore, numerous pregnancies to which I shall presently refer have followed this procedure, and I now use it as a regular clinical step in dealing with cases of sterility.

The contraindications are precisely the same as for inflation, and the procedure is the same with regard to

preparation beforehand, in addition to which an aperient is taken the night before in order to empty the bowel, thus facilitating the x-ray picture. The patient is placed in the lithotomy position and the vagina and cervix are dried and painted with iodine. The uterine tube is connected by a length of rubber tubing to a 20 ccm Record syringe, 10 ccm of lipiodol is poured into the syringe, and the piston is pressed home until the lipiodol begins to flow from the end of the uterine tube. The uterine tube is then passed into the uterus, and the cervix is compressed around it by tenaculum forceps. A length of gauze passed into the vagina serves to support the instruments and to prevent the backflow of lipiodol on to the x-ray couch. The patient is then placed on the x-ray couch and the lipiodol is slowly and steadily injected while being observed under the screen. When tension pain is complained of the object is achieved, for the lipiodol has arrived at the site of obstruction, and the photograph is taken.

Care is necessary in the interpretation of hystero-grams, for many will present the appearance of blocked tubes (Fig 3) if judged by the photograph taken at the time of injection alone. It is essential that a second x-ray picture be taken a day or two later, when it will be seen that the lipiodol is in the peritoneum, and therefore the tubes are patent. In order to obtain the fullest information about the tubes an oblique photograph should also be taken, but this should be done at the time of injection when the tube is in the uterus.

Lipiodol is absorbed and disappears from the peritoneal cavity in from seven to ten days, it disappears from the uterus by gravitation in one to two days, but when injected into closed tubes it may give a shadow for some months. In one of the patients who became pregnant there was some lipiodol in the left tube at the fifth month of pregnancy and she was later delivered of a full-time normal child in Queen Charlotte's Maternity Hospital.

When lipiodol is being used as a therapeutic measure 5 ccm is all that is necessary, as that quantity is sufficient to fill both tubes and uterus. I commenced using it in this way owing to the inefficient technique of inflation. Before Currier's apparatus was introduced I carried out inflation by means of a hand bulb and when the tubes were apparently closed I later injected lipiodol. I am quite sure that the results of inflation with that technique were often wrong, and I was surprised to find that three of the patients who had been injected with lipiodol returned later and were pregnant. Since then I have used lipiodol for sterility in all suitable cases where pregnancy has not ensued within three months of a positive inflation.

Results of 100 Cases of Inflation of Uterus and Tubes

In 51 cases the tubes were closed owing to pelvic infection in 13 of these cases the abdomen was opened for the relief of sterility.

In 22 cases the sterility was attributable to the husband. In 47 cases the woman was apparently normal and 15 of them became pregnant. Out of the 32 apparently normal women who did not become pregnant there were 8 cases in which the condition of the husband was unknown.

— One case of one child sterility each 5 and 6 years.

Therefore it would appear that 31 per cent of apparently normal women became pregnant after inflation, but while I do not suggest that the result was in consequence of inflation, I do consider that seven of the pregnancies (14 per cent) ensued so closely upon the inflation that they may be considered in the relationship of cause and effect. In dealing with a procedure like inflation we have to remember there are two factors which may nullify conclusions: (1) the dilatation of the os necessarily incurred during instrumentation, (2) coincidence.

The commonest therapeutic measure employed for cases of sterility is dilatation of the cervical canal, and it is not so many years since this was regarded as the ultimate resort. We know that a small percentage of women become pregnant after this operation, and I think it may be said in consequence of it. Now the dilatation involved in passing the uterine tube, though to a much smaller degree, may have an equally fortunate result, and this must be taken into account when estimating the value of inflation. Coincidence is a still more difficult factor to evaluate, and probably all of us have instances of it in our minds. It was forcibly brought home to me in two cases of

three and four years' sterility, where inflation had been postponed for various reasons for two to three months, and when the patients returned they were both pregnant.

It is impossible to assess the true value of inflation in these cases, and it is extremely probable that some of the cases of two years' sterility would have become pregnant later without the inflation, nevertheless the short interval between the inflation and conception in three of the cases suggests that the process played some part in the result. The sterilities of longer standing I am inclined to regard as being in direct relation, for some of these patients had less pain with subsequent periods and an increased sexual activity and

sensation. The two cases of pregnancy which occurred seven and twelve months later had certainly no relation to the procedure.

Results of Lipiodol Injection in 67 Cases

In 26 cases the tubes were apparently closed.

In 41 cases the tubes were patent and 14 of the women became pregnant.

* One woman of two years' sterility miscarried at the end of three months, but is now pregnant for the second time.

† One woman of three years' sterility miscarried at five months but is now pregnant for the second time.

Eight living children have been born and six women are now pregnant.

The cases in which the tubes were patent but no pregnancy ensued numbered 27.

Two patients had had abdominal operations, one of them was opened a second time for intestinal obstruction.

There were 2 cases of endocrine deficiency.

In 2 cases the man was defective.

There was 1 case of fibroids for which I did myomectomy.

In 4 cases I explored the pelvis and found pelvic peritonitis, appendicitis, retroversion and closure of one tube.

Sixteen cases have been done from one to four months and it is too early to decide upon the effect.

I now suggest the answer to the question in the earlier part of the paper. After inflation, with patent tubes and the patient remaining sterile for three months, are we to advise laparotomy? No, inject the patient with lipiodol and wait nine months. After inflation, with closed tubes, are

FIG 3.—The uterus and both tubes are shown but patency of the tubes is only proved by a second radiogram taken a few hours later. Notches in the tubous and left lateral wall indicate small fibroids. The patient aged 30 who had been sterile for thirteen years became pregnant three months after injection of lipiodol.

wo to attempt a plastic operation on the tubes? Yes, if after investigation with lipiodol the obstruction is found to be in the ampulla. When all this has been done there remain only the ovaries to be considered in the chain, and these organs can only be examined by abdominal operation. Are we to recommend this rather serious step? The answer must be Yes, for without it we have not carried the investigation to a conclusion.

The conditions, apart from destruction, which may be expected to hinder conception are (1) thickened tunica albuginea, (2) cystic ovaries, (3) ovarian cysts of one or both ovaries, (4) veils of peritoneum which completely shut off the ovaries from the peritoneal cavity. A thickened tunica albuginea and small cystic ovary—conditions which are associated with a chronic inflammatory process—offer little prospect of success from any operation. Incision and scarification of the thickened tunica is only too likely to induce a more extended infection in the shape of additional or added adhesions, and resection of a cystic ovary merely increases the fibrous tissue already present in a diseased ovary.

Cysts of one or both ovaries, in contradistinction to cystic ovaries, do present opportunities of success in cases of sterility, for, whatever the reason, they do possess some restrictive influence upon successful ovulation. I have operated upon six cases of small unilateral cysts in which the duration of sterility was 3, 5, 5, 6, 7, 7 years and which were followed by pregnancy within three months in four of the cases, which leaves no doubt that the relationship was cause and effect. These cases are difficult to understand or explain, for although one might consider that a unilateral cyst might by mechanical means interfere with ovulation in the ovary from which it grew, there is no apparent reason why it should interfere with ovulation from the ovary of the opposite side.

Small ovarian cysts of both ovaries are almost certainly associated with sterility, whether there be follicle-bearing tissue or not, this is probably due to the pressure and distortion produced by the cysts, whereby the ovary rarely ripens, and if they do the prospect of their gaining entrance to the Fallopian tube is poor. Exceptional cases occur where pregnancy has ensued despite the presence of bilateral cysts. I have had one case of pregnancy after removal of a cyst from each ovary.

A limited peritonitis which has veiled off the ovary completely from the peritoneal cavity is a remediable form of sterility, a case of which occurred in my practice recently.

A uniparous woman, aged 28 had not been pregnant for six years. She was cured for sterility, and later advised to have a Gillian's operation for moderate retroversion for the same purpose. She was sent to me and I found both tubes patent but there was a cyst in the left ovary and I advised laparotomy. I opened the abdomen and found the left ovary almost entirely replaced by a cyst and the right ovary shut off from the pelvic cavity by a filmy peritoneal veil. The cyst was excised and the right ovary freed and slung up loosely by a suture to the iliac brim. Four months later she became pregnant.

The Influence of Persistent Corpora Lutea on Sterility

The persistence of a corpus luteum in cattle is said to be responsible for 70 per cent of sterilities, which are known to be fairly common in herds of pure breed. Veterinary surgeons have observed that if a false corpus luteum remains unabsorbed in either ovary of a cow she does not come on heat, and neither does she conceive. Apparently the ovaries can be easily felt and compressed through the rectum in these animals, and in those which miss their heat expression of the corpus luteum is followed by heat in two to five days.

Ochsner states that expression or excision of the false corpus luteum in woman is followed by menstruation in twelve to thirty-six hours, and he gives the details in nine cases. I have no experience of this, but if the veterinary reports are correct then I should expect to find Ochsner's experience of some value in the treatment of unexplained sterility.

Now when the foregoing investigation has been exhausted, is there any other way of explaining the few, if any, remaining cases of sterility? I personally do not believe that there will be any not fully accounted for, but there is a very generally accepted group labelled "incompatibility or selective sterility."

This is the condition in which a man and wife, both presumably normal and fertile, fail to have children, but one or both, on remarriage, may succeed in procreation. It is exceedingly doubtful whether such a variety of sterility occurs, for most, if not all, of the cases quoted will not bear critical examination. In my experience I have only met two cases in which I was driven to this conclusion—in one case after a laparotomy, in the other case, much more doubtful, without the operation.

In the complete case a woman, aged 28 had a child before marriage. She subsequently married another man who was of strong physique, normal semen and high fertilizing power. She was normal in all respects including patency of the tubes to gas and lipiodol and I recovered living spermatozoa from the cervical canal. I opened the abdomen and found a normal pelvis with two healthy ovaries, one of which had recently ovulated. She remains childless.

I believe that the cases usually described as "incompatibility or selective sterility" are really cases of combined relative sterility, in which both the man and the woman are of low fertilizing power. This is a group of cases in which no cause can be found for the sterility, nevertheless, when we come to assess the clinical findings, we are struck with the fact that functionally neither of them is normal. In the man we are probably surprised to hear of the infrequency of coitus and his indifference to the act, the semen contains relatively few spermatozoa, and their motility ceases sooner than one is accustomed to find in a vigorous specimen. A report on these men frequently shows that they are of poor physique, the penis is small and sometimes webbed, the testicles are small and not infrequently associated with a varicocele, these conditions have no relationship to venereal disease or other constitutional disease—they are indicative of poor specimens of the race. It is impossible to regard these men as sterile, for they have living spermatozoa, though few, and if they were married to healthy women of normal fertilizing power it is probable that conception would occur. Similarly when we sum up the woman we find that she is deficient in sex sense. She may be cold and experience no desire for coitus or orgasm, physically she is perhaps just not pleasing—thin, sallow, and angular in some cases, or a little too plump, with a growth of hair in unusual parts of the body. The catamenia are often regularly irregular, scanty, and associated with dysmenorrhoea. All these minor defects are not sufficient to render these women barren, nevertheless they are undoubtedly sterile when mated to men of the same class, and I believe that all cases of selective sterility are really cases of combined relative sterility.

DIAGNOSIS AND TREATMENT OF STERILITY IN THE MALE

BY

KENNETH WALKER, F.R.C.S.,

Surgeon in Charge Genito-Urinary Department, Royal Northern Hospital, Surgeon to St. Paul's Hospital, Lecturer in Venereal Diseases, St. Bartholomew's Hospital

THE fact that I have the honour of taking part in this discussion on sterility is not without significance. It is an indication that the equality of the sexes as regards responsibility for the presence or absence of children is now fully recognized. Fifty years ago the treatment of the barren woman began with a curettage, nowadays no responsible gynaecologist will embark on any operation, however trivial, until the husband has been overhauled. The necessity for this is self-evident. Amongst 253 unfertile unions Dr. J. Sturdivant Read found 167 instances of impaired fertility in the male. This, of course, does not necessarily mean that those 167 husbands were entirely responsible for the absence of children, for in some cases their deficiency was but slight, but any lowering of fertility in the male may become important if at the same time there exist also some obstacle to conception in the

* A paper read in a discussion in the Section of Obstetrics and Gynaecology of the Annual Meeting of the British Medical Association Cardiff 1928.

female. For this reason attention must be paid to minor faults in the husband as well as to conditions of complete sterility. Lode has estimated that some 200,000,000 spermatozoa are thrown into the female passage in a single ejaculation. Of this huge multitude of aspirants to immortality only one, if conditions be favourable, will succeed in reaching and meeting with the descending ovum. A reduction in the number of spermatozoa ejaculated will diminish the chances of union taking place, a lowering of the vigour and mobility of the candidates will have the same effect. For this reason the discovery of a condition of oligospermia or of oligozoospermia in a husband is of great importance. Should there exist at the same time any impaired fertility in the wife the importance is increased still further.

In my paper I shall attempt to deal not so much with well established medical facts, such as the part played by gonorrhoea in the causation of sterility, but with ideas that are as yet unproved—ideas that may be regarded as being at the growing point of our knowledge. As yet we know so little about our subject that it behoves us to look at it from every angle and to strive to make progress wherever it may seem possible to take a few steps forward. But because it is above all necessary in a discussion like this to deal with points of practical importance I shall use as my text the case sheets of patients I have had to deal with in my consulting room, and thus avoid the risk of becoming too theoretical.

TYPES OF STERILITY

On examining the records of these husbands, the vast majority of which were referred to me for examination by gynaecologists, I find that out of a total of 57, only 25 could be considered absolutely normal. Of the 32 that were deficient 18 were absolutely sterile, 6 showed a very marked impairment of fertility, and 8 minor degrees. The results of the examination of the semen of these 57 cases may be tabulated as follows:

Normal healthy semen	25
Oligospermia	2
Oligozoospermia	6
Oligonecrozoospermia	6
Azoospermia	18

Before considering the causes responsible for these deficiencies in the semen a few preliminary comments must be made. In the first place it must be pointed out that oligospermia, or a reduction in the total quantity of semen ejaculated, is not necessarily pathological. It occurs normally in old age, and also when coitus has been repeated after a short interval. For this reason before examining a condom specimen a week of sexual abstinence must be enforced. It is also probable that in certain sensitive individuals the wearing of a condom hampers the freedom of the sexual act and diminishes the quantity of semen ejaculated so that a diagnosis of oligospermia must always be received with caution.

Oligospermia, or a deficiency of living spermatozoa in the specimen examined is more significant. But again it must be remembered that the semen is made up of the secretions of other glands than the testis and that the relative bulk of fluid contributed by the accessory glands varies from one coitus to another. An oligozoospermia should therefore only be diagnosed if poorness in spermatozoa is a feature of every specimen examined.

Oligonecrozoospermia usually indicates the existence of an inflammatory focus somewhere in the genital tract, and most commonly in the vesiculae seminales.

CAUSES OF STERILITY

Speaking generally, it may be said that sterility in the male is more frequently the result of acquired conditions than of congenital abnormalities, and that in the production of these venereal disease plays the chief part. It is indeed probable that gonorrhoea alone accounts for some 50 to 70 per cent of cases of male sterility. Beazer's observations on the after history of German soldiers who had suffered from gonorrhoeal epididymitis and had subsequently married are well known. He found that 23.4 per cent of men who have a history of unilateral epi-

didymitis were without children at the end of three years of married life, and that where there was a history of bilateral infection this figure rose as high as 41 per cent. When the length and fineness of the ejaculatory duct are considered it is not surprising that atresia should be a frequent sequel to infection. But, quite apart from blocking of this duct, gonorrhoea may be the cause of sterility through damage to the ejaculatory canals and seminal vesicles.

However, the importance of gonorrhoea as a cause of sterility is widely recognized, and I do not wish to take up your time in dwelling on the obvious. I would rather attempt to break new ground and to discuss aspects of this interesting subject which are less familiar. In 8 of the 24 cases of oligonecrozoospermia and azoospermia cited above, no history of venereal disease existed, so that some other explanation had to be found for the absence of healthy spermatozoa in the semen. In one of these there was a staphylococcal infection of the genital tract. The patient was an officer who had been occupied for two years in the work of unloading mustard gas shells, as a result he had developed a bad staphylococcal infection of the skin which had subsequently spread to his urethra. In a second patient, a streptococcus was obtained from the semen, and it is possible that this plus age was responsible for his sterility. But before dealing with these individual cases it will be best to pass in review the conditions that may affect spermatogenesis.

In the first place it must be recognized that the spermatogenic function of the testicle is far more sensitive to outside influence than is that of the internal secretion. For example, a comparatively small dose of x rays will produce aspermatogenesis, whereas long and repeated exposures will be required before any effect is produced on the internal secretion. In the same way a comparatively mild infection of the testicle will be sufficient to cause degeneration of the tubules while leaving the cells of internal secretion untouched. Kyrle, as a result of the examination of a thousand testicles, states that the testicle of a man is sensitive to such a degree that it is hardly possible to find a normal testicle in adults who have died of acute infective diseases, such as pneumonia. Yet in spite of the damage done to the tubules none of Kyrle's cases gave indication that there had been an upset in the function of the internal secretion. How long the damage done to the tubules by a severe general infection persists, and whether it is ever permanent, are questions difficult to answer. I have had, however, one patient with aspermatogenesis for which I could find absolutely no explanation beyond an attack of pneumonia and of acute appendix trouble some four or five years previously.

But degenerative changes are produced in the seminiferous tubules not only by the toxins of an acute infection but also by poisons such as alcohol. Bertholet and Weichselbaum have both laid stress on the disappearance of spermatozoa from the tubules in cases of chronic alcoholism. Laboratory experiments on guinea-pigs also support the view that alcohol may reduce fertility.

We will now consider in detail the various conditions that may affect the output of spermatozoa from the tubules.

(a) *Infections*—It has already been noted that spermatogenesis may be diminished or even abolished not only by local inflammatory conditions such as orchitis and epididymitis, but also by infection elsewhere in the body. Belfield and others have shown that organisms in the blood stream may be excreted by the testicles and seminal vesicles. Embryologically the vas is developed from the Wolffian duct or primitive excretory system, so that it is not altogether surprising that organisms in later life should occasionally find their way out of the body along such a route.

(b) *Endocrine Disturbances*—The functional connexion between the reproductive organs and other glands of internal secretion is well known. Changes in the tubules may therefore be the result of diseases of the endocrine glands. Dr Evelyn Howerl found that the injection of rats with various preparations of suprarenal cortex produced marked degeneration in the tubules of the testis. Feeding with thymus gland extract had a similar result. Conversely, in certain cases of aspermatogenesis the formation

of spermatozoa may, according to Hühner, be brought about by feeding with anterior lobe pituitary extract

(c) *Heat*—N Fukui,² in an article on the action of heat rays on the testicle, stated that he had found that, after subjecting the testicle of a rabbit to the action of heat, definite regressive changes occurred in the seminiferous tubules, changes that were similar and just as intense as those brought about by the action of x rays. For the purpose of his experiment he employed sunlight, powerful arc lights, and warm vapour baths. Histological examination of the testis after exposure to these agencies showed that a selective destruction of the generative cells of the tubules had taken place, leaving the cells of Sertoli and the interstitial cells of Leydig intact. It is interesting to note that a comparatively low temperature was sufficient to produce these changes, thus exposure of the scrotum of the rat to afternoon sunlight in the summer for a period of three hours gave rise to the phenomenon termed by the writer "heat testicle." A warm bath of 45° C for the same period of time produced identical changes. So far as I know, Fukui's experiments have not been confirmed, but if his observations are correct they would indicate that a high temperature may sometimes be a factor in the production of sterility.

It has, of course, been suggested that the reason for the descent of the testicle into the scrotum in man is on account of the fact that the optimum temperature for spermatogenesis is below that of the abdomen. Crew, who supports this theory, points out that the scrotum, with its dartos and cremasteric muscles, acts as an excellent heat-regulating mechanism. If Dr Fukui's observations are correct, it should certainly be possible to obtain corroboratory evidence of the unfavourable action of heat on spermatogenesis from a study of the fertility rate of men employed in such occupations as stoking and cooking. But although prolonged exposure to sunlight may bring about degenerative changes in the tubules on account of its heat rays, it is probable that the rays of the other end of the spectrum have a favourable action on spermatogenesis. In birds the testicles increase enormously in size in the early spring months, and there are reasons for believing that sunlight acts as a stimulus to the rapid development of the tubules occurring at this time.

(d) *Diet*—During the last three years much work has been done on the influence of diet on the function of the tubules. C. B. Paul³ was perhaps the first to show that fertility is affected by diet. Later, T. B. Osborne and L. B. Mendel⁴ noticed that although animals fed on artificial diets grew vigorously to adult size they were, with very few exceptions, sterile. Microscopic examination of the testes of these animals showed that there had occurred a total degeneration of all the germ cells. Some two years ago Karl E. Mason⁵ made an extensive histological study of the sterility produced in albino rats by means of a deficient diet. The rats were fed on the following menu: casein 18 per cent, starch 54 per cent, laid 15 per cent, butter-fat 9 per cent, salt mixture 4 per cent, plus yeast tablets 0.4 gram daily. This diet, which was sufficient for the growth and vigour of the rats, invariably led to sterility. Histological examination of the testes at various times after the rats had been placed on the above-described regimen showed the following changes. In the early stages all that was noticed was that the spermatozoa lost their individuality and became clumped together in irregular masses, in which could be seen signs of chromatin degeneration. At a later stage most of the spermatozoa disappeared and signs of degeneration could be detected in the spermatids. Last of all the spermatocytes and spermatogonia were affected. As a result of this and of many similar experiments the existence of a special vitamin E, that is essential to reproduction, was postulated. If the rats thus rendered sterile were given lettuce leaves or extract of wheat regeneration of the tubules occurred with reappearance of spermatozoa. It is well known amongst veterinary surgeons that dogs frequently become sterile on a diet of cooked meat and biscuits. If for these are substituted raw meat and raw carrots fertility is regained. A similar increase in breeding capacity is brought about in stalled cattle by turning them out on to fresh grass.

All these observations emphasize the part played by diet in the production and in the treatment of sterility. We will do well to take to heart this lesson from veterinary science and to apply it in a modified form to the treatment of infertility in man.

(e) *Local Conditions*—The functions of the tubules may be influenced by local changes, as well as by the general conditions already cited. In one of my patients azoospermia was easily explained by the fact that he had been born with bilateral retained testes. This had been treated by removal on one side and orchidectomy on the other. The operation was a success only from the point of view of the position of the testicle in the scrotum, it had failed to restore the spermatogenic function of the tubules. In four other cases operations had been performed in the neighbourhood of a testicle, or of its vas (one varicocele, one bilateral hydrocele, one for unilateral hernia, and one for the extraction of a bullet lodged in the neighbourhood of the groin). It is impossible to be certain whether these operations had any bearing on the condition of azoospermia. My own opinion is, however, that an operation for varicocele is not without danger to spermatogenesis. Profound changes not infrequently follow ligation of the pampiniform plexus, changes in which the seminiferous tubules are extensively involved. A radical operation for hydrocele is not so likely to damage the function of the testicle, but the existence of the hydrocele generally indicates an abnormal state of the testicle.

Before proceeding further I should like to refer to a matter of considerable interest—namely, artificial insemination.

ARTIFICIAL INSEMINATION

This method of treating sterility has been practised for a long time both by gynaecologists and by veterinary surgeons, but when we examine the results obtained by these two classes of practitioners we find that they are utterly different. I am told by Major Pugh, F.R.C.V.S., that amongst cattle artificial insemination is at any rate as successful as is natural sexual union. Yet when I inquire amongst gynaecologists I can find no record of their having obtained positive results. The late Herbert Williamson confessed to me that the net result of 33 artificial inseminations carried out by him was one doubtful miscarriage. What is the explanation of this failure to inseminate human beings successfully? My own opinion is that it is due to the difference in technique that is employed in the two cases. In veterinary practice insemination is always preceded by sexual stimulation of the female. The bull is allowed to toy with the cow, and as a result of this there is an outpouring of her sexual secretions, that these secretions are favourable and perhaps even essential to the life and vigour of the spermatozoa would seem to be established. It is a saying amongst farmers that a cow should be served before her udders are dry. The complete disappearance of her milk is accompanied by an involution and drying up of the genital organs. Major Pugh tells me that when he is called upon to treat a cow that shows signs of this involution he starts off by stimulating the flow of genital secretions. This can be done indirectly through the breasts, the actual method he employs being that used in the treatment of "milk fever"—namely, the pumping of air down the udders. As the result of this apparently crude procedure a flow of sexual secretions is provoked and the temporary sterility cured. All these facts emphasize the importance to fertility of the secretions of the genital passages. In human practice we have disregarded this factor. Our patients are often inseminated while under the influence of an anaesthetic. There has been no preliminary stimulation, no sexual excitement, no outpouring from the accessory sexual glands. We sow our seed on unprepared ground and the result is failure. We must take a hint from veterinary medicine and change our technique. There are other methods of stimulating the genital secretions than those of the veterinary surgeon. I am unaware of the technique of artificial insemination employed by the late S. J. Aaron⁶, but it is possible that he appreciated more fully than some of us have hitherto done the necessity of preparing the soil for the reception of the seed.

DIAGNOSIS AND TREATMENT

The diagnosis of sterility rests on the examination of the patient and of the semen. If necrozoospermia is found a search must be made for signs of infection in the genital tract. Azoospermia means either that there is a blockage in the ducts or else that spermatozoa are not being formed. To differentiate between the two conditions the testes must be punctured with a hypodermic needle and the extracted fluid examined microscopically. Should spermatozoa be present a searching investigation must be made to discover the site of the obstruction. Most frequently this is situated either in the epididymal canal or in the ejaculatory ducts. A history of epididymitis and the persistence of a thickening in the lobus minor are strongly in favour of the former. If neither is found, posterior urethroscopy should be carried out with, whenever possible, catheterization of the ejaculatory ducts. Additional information may be obtained by injecting a dye into the vas at the neck of the scrotum and watching for its appearance in the urethra.

Unfortunately surgery as yet offers little help for the treatment of stenosis, whether it be in the epididymis or in the ejaculatory ducts. Numerous operations have been devised for effecting a fresh anastomosis of the vas with the epididymis so as to overcome any blockage that may exist in that situation. Successes, however, are of the greatest rarity owing chiefly to the difficulty of ensuring that the anastomosis remains patent. Obstruction in the ejaculatory ducts may sometimes be overcome by catheterization and by energetic treatment of a residual infection in the prostate by means of massage.

If sterility be the result of aspermatogenesis a careful search must be made for its cause. The history of past illnesses, the habits, mode of life, and diet of the patient, must all be reviewed and every effort made to improve the general health. The fact that conception frequently occurs at the end of a long summer holiday is an indication of the close relationship that exists between general physical efficiency and fertility. Veterinary surgeons deal with sterility in stalled animals by letting them run wild in the fields. If bank clerks and other followers of sedentary occupations could be treated similarly their fertility would undoubtedly be increased.

The importance of infections, whether in the genital tract or elsewhere in the body has already been emphasized. All septic foci must therefore be dealt with however remote may seem the connexion with the patient's sterility.

Endocrine therapy is worth trying in cases of aspermatogenesis even when the ductless glands do not appear to be implicated. Anterior lobe pituitary extract is by far the most useful of the endocrine products, and should be persevered with for six months. At the end of this time the testes should again be examined for the presence of spermatozoa. Drugs, except when given as tonics, are, so far as I know, useless. It has been said that testicular grafts have a stimulating action on the patient's own glands but as I have not used them for this purpose I can neither confirm nor refute this statement. If signs of hypothyroidism are present treatment with thyroid extract is likely to have a stimulating action on the tubules.

In view of the part played by sunlight in the seasonal growth of the testicles of birds I am tempted to think that small doses of ultra-violet light might exert a favourable action on some cases of aspermatogenesis. However, as yet I have no observations of this to report to you.

CONCLUSION

In this paper I have laid emphasis on the type of sterility that is unassociated with any obvious physical defects. I have done so deliberately because I feel that in the past we have occupied ourselves too much with questions of anatomy, too little with the physiology of reproduction. We have searched for displacements of the womb and obnormalities of the cervix, and having corrected these have felt satisfied that we have done all that is within our power and that the rest must be left to Nature. But it is not enough that the spermatozoa should enter the uterine cavity and that the ovum should be thrown into the Fallopian tube. For the meeting and

fusion of these two cells certain conditions are necessary, concerning which we at present know little or nothing. Wolbarst's insistence on the importance of examining the behaviour of spermatozoa when in contact with the female secretions is a move in the right direction. But more than this is necessary. We must understand more fully the part played by the secretions of the secondary glands of sex. We must study the reaction of the spermatozoa to the various fluids it meets in its perilous journey from the seminiferous tubules to the ovum, the secretions of the epididymis, the vesicles, the prostate, the cervix, and the uterus. We must discover the reason of our failure to inseminate a healthy woman with what are apparently healthy spermatozoa.

We are struggling to treat sterility with an utterly insufficient knowledge of the physiology of impregnation—shooting arrows haphazard into the air in the hope that one perchance may reach its mark. If we are to obtain the exact knowledge on which a scientific treatment can alone be based we must work, not apart, as people viewing the problem from the point of view of the gynaecologist or the genito-urinary surgeon, but together, as colleagues engaged on a single task. Only then can we hope to fill in some of the gaps in our knowledge and to establish our treatment on a scientific basis.

MEDICAL, SURGICAL, OBSTETRICAL

ACUTE IDIOPATHIC DILATATION OF THE STOMACH

The following case may be worth of record on account of its comparative rarity, the unusual physical signs presented, and the nature of the findings at necropsy, which were inconsistent with the commonly stated etiology.

On July 18th 1928, the patient a girl 24 years of age with no previous history of ill health was suddenly seized with vomiting which persisted until shortly before her death three days later. During the previous week her appetite had been deficient and her general condition somewhat below its usual standard. For three days there was absolute constipation.

Condition on admission to Hospital July 21st 1928.—The patient was collapsed. She complained of abdominal pain and suffered from thirst. Moderate quantities of brown fluid were vomited at short intervals. The abdomen was not distended though it was a little fuller in the hypogastrium than in the epigastrium. A wave synchronous with the cardiac systole passed from the left hypochondrium to the hypogastrium and a splashing and gurgling sound also synchronous with systole was distinctly audible without using the stethoscope. On auscultation with the stethoscope sounds were heard resembling those described as Hippocratic succession in the chest. The apex beat of the heart was visible in the mid axillary line and was diffuse and slapping in character. The right border of the heart was one inch to the right of the sternum but there was no visible epigastric pulsation. At the necropsy the most noteworthy features were: (1) The stomach was so enormously distended that the greater curvature sat on the brim of the true pelvis where it bent on itself a portion returning towards the duodenum. (2) The distension extended along the entire duodenum and did not cease abruptly—that is to say the distended gut gradually gave place to the collapsed lesser bowel about a foot from the duodeno-jejunal flexure. (3) A ring of lesser dilatation indicated the position of the pyloric sphincter. (4) The whole of the small intestine was collapsed and proflapsed in the pelvis minor. The mesentery was longer than normal. The thymus gland weighed 1/3 oz and the thyroid gland 1/4 oz. In the suprarenal gland there was no depletion of the cortical hypod. There was no other relevant pathology.

From a consideration of the facts it would seem justifiable to suggest that, although there was in fact a prolapse of the small gut into the pelvis, the mesentery was not the constricting agent. Again, because of the absence of a definite delimitation of the distension it may be suggested that the cause rather than being on affairs of simple mechanics may be related in some way to the nervous mechanism for the control of tonus of the gut.

I am indebted to Dr W H Thompson for permission to publish this case.

FOUR CASES OF GLIOMA RETINAE IN ONE
FAMILY

GLIOMA retinae is a rare condition, in the course of the last five years only 11 cases have been treated at the Royal Eye Hospital. During this time 114,764 patients were seen, this hospital, being the only London eye hospital south of the Thames, draws its material not only from South London, but from the suburbs and a large area of the country. The occurrence of four cases of glioma retinae would seem to be worthy of record, the mother of this family has had five children, of whom one died at birth and one is sound. The clinical histories of the other three children are as follows:

Leonard was born in 1919. In August 1921, he was found to be suffering from a glioma of the right eye, which was enucleated. In January, 1923 he was readmitted with a glioma in the left eye. The white mass was quite evident by focal illumination, although he could still see to play with his toys in his cot. On removing this eye I found a mass of growth as big as a hazel nut projecting through the sclerotic. In spite of the orbit having been eviscerated the growth recurred *in situ* in the following May, and he did not long survive.

Walter was born in 1921. At the age of three months the right eye was removed for glioma. He remains healthy.

Ernest was born in March 1928. I saw him in May with a glioma in the right eye, which was enucleated.

This remarkable family history therefore shows four children surviving their birth, three have been affected by retinal glioma, two losing one eye each, and one losing both eyes and subsequently succumbing to a recurrence.

We can trace this terrible misfortune for the mother to an operation which was performed in May, 1897, when the right eye of a child aged 2 years and 3 months was removed for glioma, this patient became later the father of the family here reported.

For no one who has seen a child dying from glioma there can be no alternative but to remove the eye, even if it be the only one. From the individual point of view—from that of the child perhaps, from that of the parent certainly—it is the right and only course, but what a disaster for the community and the welfare of the race! I fear this is only one instance of what the progress of surgery and medicine is capable of doing for man by preserving individuals suffering from an hereditary taint, who would, in the ordinary course of nature, be eliminated.

T. W. LETCHWORTH, M.B., F.R.C.S.,
Surgeon Royal Eye Hospital.

PHTHISIS AT THE AGE OF 85

THE following case of pulmonary tuberculosis in a woman aged 85 seems worthy to be recorded.

A widow, aged 85 whom I have known for several years but who has never previously consulted me professionally, sent for me in November 1927 for a slight sprain of the ankle. Her mother and father had been healthy and had lived to old age. Her brother and two sisters were healthy also. The patient had been a widow for forty years. She had had five children of whom four were living and healthy. She had always had very good health and could not remember having seen a doctor since her last confinement.

While attending her for the sprained ankle she mentioned that she had wheezing and a slight cough. The cough had commenced in June, 1927 and had continued off and on. She felt very annoyed that she should be troubled with it and could not understand why she should be ill since up to then she had been very active, taking long walks and frequently visiting theatres and amusements at night. I examined her chest and found a general bronchitis which is common in old people. The temperature was normal and the sputum scanty, but difficult to expectorate.

During December she became worse, with pyrexia up to 101° F. but mostly between 99.2° and 100°. In January 1928 the left upper lobe began to break down and night sweats commenced. The sputum became mucopurulent and on examination tubercle bacilli were found in large numbers. In February she had a brisk haemoptysis lasting three days. Since then the disease has advanced rapidly and now practically the whole of the left lung is involved and the right apex in addition. I have had the sputum examined on three separate occasions and it has always been strongly positive. She is rapidly losing ground and the pyrexia is constant.

I can trace no reason for the disease coming on so late in life, she has not lived with anyone who has had similar trouble. The only thing I can find is that she has always had in the house a number of animal pets, especially cats, but these, she declares, have always been healthy.

Reports of Societies.

MEDICAL AMBITIONS AND IDEALS

PRESIDENTIAL ADDRESS TO THE MEDICAL SOCIETY OF
LONDON

At the first meeting of the session of the Medical Society of London on October 8th, Dr. WALTER CARR, the president, delivered his address from the chair. At the preliminary business meeting of the Society it was announced that John Ward's diary, one of the valuable possessions of the Society, had been sold for £10,000, of which sum £9,000 had been invested and £1,000 devoted to improvements in the library.

Dr. Walter Carr, who mentioned that he had been a Fellow of the Society for just upon forty years, took for his subject "Medical ambitions and ideals." Medical men, he said, were necessarily moved by the same impulses as others, although their ambitions might be somewhat more altruistic and less directly selfish than those of the majority of their fellows. Three motives in particular influenced those who aimed at becoming leaders or rulers in any department of life. The first was the love of power and influence, which really meant the desire to rule over other people, even the acquisition of wealth was generally coveted, not for its own sake, but as a necessary step towards the attainment of such authority. The second motive was the desire to bring about uniformity. Here man differed from nature, for whereas the keynote of nature was diversity, uniformity was always man's ideal, and the more capable a man was, and the more convinced as to the rightfulness of his views, the more determined was he likely to be, especially as he got older, to make others think, talk, and act as he did himself. Finally a man liked to convince himself and other men that in exercising power he was not acting from selfish motives, but was really anxious to benefit others. The most typical and successful example of the exercise of these three motives on a large scale was afforded by the Catholic Church in the Middle Ages, when it attained supreme power over practically every department of human life. It established uniformity of belief by ruthlessly extirpating every form of heresy and schism, and justified all its deeds of tyranny and cruelty on the plea that it was acting in the best interests of its victims. Now that the power and influence of the mediaeval Church had declined, it would seem that the medical profession might aspire, perhaps, to replace it!

A Medical Bureaucracy

The speaker then, adopting a tone of gentle irony, indicated how medical men might attain these ambitions. Power over their fellow men would, of course, be gained through a State medical service, at the head of which would be the chief medical officer to the Ministry of Health—not the Minister of Health himself, who, to his chief medical officer, would be as king to cardinal. Indeed, the position of the chief medical officer would be like that of Pope in the mediaeval Church, under him would be inspectors and consultants—at present called regional medical officers—who would correspond to bishops, while district medical officers, to each of whom would be allotted the care of a certain number of people, would be like parish priests. Separate staffs of doctors would be trained to take charge of the State and municipal hospitals, to act as medical officers of health, and to be responsible for the many departments of preventive medicine.

The question of health entered in some way into practically every part of a man's life and being—from the moment of his conception to the final disposal of his remains after death. Therefore the State, through the medical profession, would not only provide ante-natal care, would ensure that every baby was born in a suitable institution, and would look closely after the individual through infancy, childhood, and school life, but would have the final voice in settling his vocation (this would be determined by the school and family doctors in consultation with the psychologist), his hours of labour, length of holidays, age of retirement,

and so on. Above all, the State would decide upon his fitness for marriage and upon the suitability, physical and mental, of his proposed partner in life. No marriage would be permitted without previous medical inspection, and the newly married couple might be told that the State expected them to produce children at certain intervals. State authority would be necessary to support the doctor's decisions, especially to compel vaccination or inoculation, not only against small-pox, but against any disease for which this might be considered necessary, and to enforce the performance of an operation if such was deemed advisable by the medical attendant. A beginning had already been made in this direction by the taking of proceedings in police courts against parents who perversely refused to consent to the removal of their children's tonsils and adenoids, and it had also been proposed in Parliament to compel patients to continue treatment for venereal disease until they were cured.

Professional Orthodoxy

With reference to the second ideal, that of establishing professional uniformity and orthodoxy, it was obvious that unqualified practice of every description (including the sale of potent drugs otherwise than on a doctor's prescription) must be rigorously suppressed. Unqualified quacks would be drastically dealt with, the qualified quack would be a more difficult problem. Any heresy or schism in the profession would be extirpated at its earliest commencement. Uniformity and orthodoxy would be maintained by a strict control on trade union lines and by conferring increased disciplinary powers upon the General Medical Council. Any practice which was seriously heterodox might come within the famous term, "Infamous conduct in a professional respect." Research would be encouraged, but on strictly regulated lines, so that while minor discoveries would be welcomed, those of a revolutionary character would probably meet with a very cold reception from the senior bureaucrats, who would necessarily control all the work of their juniors. Age, particularly when combined with power, was always conservative. This was true even of individuals, and was still more true of groups. The Harveys, Pasteurs, and Listers of the future would have a poor time under bureaucracy, and would be fortunate if they escaped final expulsion as heretics and law-breakers.

In all this insistence the profession would have no difficulty in persuading itself—and would therefore be increasingly enthusiastic in persuading other people—that its aims were absolutely altruistic, and that it was exerting a beneficial authority entirely in the best interests of the community. In expensive moments it was customary to point out that the medical profession furnished a unique example of a profession doing its best to destroy the source of its own livelihood by trying to prevent disease. This was repeated so many times and on so many occasions that it might even come to be believed. But as a matter of fact there was no need for the least alarm as to the material prospects of the profession. It would always take at least as many doctors to prevent disease as it took at present to cure disease after it had developed. It might be that in future more men would be engaged on the preventive side and correspondingly fewer on the curative, but this change would take place so gradually as to cause no inconvenience.

The Dangers of Autocracy

The ideal which he had sketched might seem a glorious one for everybody concerned, but he hoped it would never be attained, both for the sake of the public and in the best interests of the profession. It had certain obvious drawbacks. The first was the danger that the possession of autocratic power—no matter how beneficent in its intention—inevitably converted a man into a tyrant. No one man or body of men was fitted to exercise uncontrolled power. The better and nobler the motives and objects of such exercise the worse it became, because that moral conviction made those concerned all the more intent on carrying out the object, no matter at what cost. As Sir Clifford Allbutt once said, "Conscience without enlightenment has to account for some of the darkest chapters

in human history." Another danger was that any form of tyranny was certain sooner or later to give rise to reaction which might do incalculable harm and set back the clock of progress. Again, enthusiasm was very liable to degenerate into crankiness, and an enthusiastic crank at the head of a medical autocracy might do an enormous amount of mischief. There were, for example, many enthusiasts who would be quite prepared to make compulsory such a measure as inoculation against influenza, especially in schools, even though its beneficial effects were far from certain. Experience was not nearly definite enough to justify one in advising let alone insisting upon, this as a precautionary measure. A scheme of inoculation was carried out most carefully in a large public school, out of 350 boys, 60 per cent were inoculated just before the Christmas holidays. On the reassembling of the school 113 boys were attacked by mild influenza, and 60 per cent of the victims were among those who had been inoculated. There was no difference whatever in the character of the illness as between those who had been and those who had not been inoculated. The inoculation did not appear to have exercised any influence in preventing or modifying the outbreak, and it was not surprising that at that school there was no suggestion that the experiment should be repeated. But under a medical autocracy it would almost certainly be a long and difficult matter to bring about changes in established official procedure.

Mild Small-pox and Vaccination

Dr Carr also raised the question whether it was necessary to maintain an elaborate and expensive system of isolation for small-pox in view of the extremely mild character of that disease during recent years. Let it be granted that vaccination did for a certain number of years protect against small-pox. But so far as he could gather the present form of small-pox rarely gave rise to pitting or made those suffering from it feel really ill. In 1926 the number of deaths attributed to small-pox in England and Wales was 18 but in the view of the Ministry of Health this was an overestimate, and the true figure was 11. In 1927 there were 14,000 cases and the deaths numbered 47 but no official particulars were yet available as to these deaths. Under the existing system of registration of deaths a considerable number, perhaps the majority, of the deaths recorded from small-pox were not due really to that disease at all, but were automatically assigned to it just because a patient already infirm, or perhaps even suffering from some mortal disease, happened to contract a mild attack during the last weeks of his life. Was small-pox nowadays a more serious disease than chicken-pox and did it call for any greater attempts at prevention and isolation, in the vast majority of outbreaks, than did the latter disease?

In conclusion, Dr Carr remarked that a medical autocracy would in the long run be disastrous for medical men themselves, because no matter how much power the profession as a whole might acquire, its individual members, even those most highly placed, would merely be slaves in or of the organization they had themselves created. Individualism, at present one of the chief glories of medicine, would be destroyed, research would be "to order" instead of being spontaneous, and would be restricted within defined limits, initiative would be extinguished, originality would be discouraged, and in enslaving others we should ourselves become the greatest slaves. "What we now most need is first humility, not to be puffed up with the little knowledge we have gained but fully to realize the vastness of the ignorance which surrounds us on every side, and the infinite complexity of the problems awaiting solution, and secondly, to maintain our professional freedom, which assuredly will be extinguished if we become mere units in the State medical service of a socialist commonwealth."

A vote of thanks was moved by Mr Warren Low, who said that it was always a delight to listen to Dr Carr, although he was at times a little uncertain whether Dr Carr was not "extending the nether extremity" of his audience. After Dr E. M. CLENDER had seconded the motion, and it had been adopted with applause, Dr Carr said he knew that what he had presented was in many respects unorthodox but on that very account he hoped it would stimulate thought and reflection.

Reviews.

THE GENESIS OF EPIDEMICS

ALTHOUGH the literature of epidemiology is large, the number of modern writers who have devoted separate volumes to the general theory of epidemics is relatively small, even, if we confine ourselves to those who have had wide practical experience of epidemic happenings, absolutely small. Colonel C. A. GILL, I.M.S., falls within the last-mentioned category. He has had extensive field experience and has already won an honourable reputation as a scientific investigator. His book on *The Genesis of Epidemics*¹ is the fruit of long study and contains much valuable information. In the first part of the book, after submitting some definitions and briefly reviewing doctrines and methods of inquiry, the author propounds the hypothesis that in the genesis of an epidemic four factors are involved—namely, (1) a reservoir of infection, (2) a parasite, (3) an immunity factor, (4) a transmission factor. Thus he calls the "quantum" theory of epidemicity. In the second part the known facts respecting malaria, influenza, and plague are described. Those respecting malaria are set out in considerable detail, and this section of the book, altogether apart from any matters of theory, is a valuable summary of research work, a good deal of it the author's own. The third part of the book discusses epidemics more at large, but with frequent references to the detail of the second part. Part 4 treats of the bionomics of disease, and Part 5 is a short summary of some conclusions.

In the reviewer's opinion Colonel Gill's objective studies, particularly his account of what actually happens during the progress of an epidemic of malaria and of the means by which the state of the population at risk (measure of intensity of infection, of degree of immunity, etc.), and the changes of that state, may be assessed, are important contributions to epidemiological knowledge, and particularly welcome to those epidemiologists without first-hand knowledge of the facts. The same remark applies to Colonel Gill's meteorological and climatological studies, although it is possible that specialists in physical meteorology and certain that expert statisticians will find lacunae in his knowledge. Nobody, however, who voices before the criticism of the specialist would write on epidemiology, and no specialist worth his salt would press hardly on inevitable defects.

As an exponent of theory, Colonel Gill, partly owing to literary disadvantages—his style is too reminiscent of the official "minute," wherein "I think" becomes "it is thought," to be attractive—is not wholly successful. Accounts of his theory are rather redundant and sometimes so expressed that the theory is reduced to a truism. That is evidently the case with our own brief summary above. The four factors named include every theory which has ever been propounded, and, of course, their co-operation will "explain" every epidemic, but only in the sense that a dormitative virtue explains the properties of opium. Colonel Gill is not of course, really preaching so empty a doctrine. What we take to be his serious thesis is that the genesis of epidemics can be satisfactorily described in terms of quantitative variations of measurable factors, and that in particular it is not necessary to suppose that qualitative changes in the parasite factor are involved. Thus to take a fairly clear-cut example, in the report upon the pandemic of influenza, 1918-19, published by the Ministry of Health data collected in different towns and institutions showed the flattest contradictions in respect of the immunity conferred by passing through an attack of influenza. In Leicester it appeared that only 4.9 per cent of those attacked in the summer were again attacked in the autumn, while 15.4 per cent of those not previously attacked took influenza in the autumn, but in Manchester the autumn attack rates upon those attacked or not attacked in the summer were nearly the same—namely, 9.9 per cent and 10.1 per cent. The authors of the report cast about for a means of reconciling these con-

tradictions, and suggested that the immunizing properties of the strains involved in different local epidemics might be different. They produced no direct evidence of this, and Colonel Gill has no use at all for suggestions of this kind. Most readers are likely to find Colonel Gill more successful in showing the weaknesses of the support facts afford for hypotheses of biological variation in the parasite factor than in setting up a rival hypothesis. Thus one of the remarkable features of the great pandemic of influenza was the abrupt change in the age distribution of deaths which characterized it. Why was it abrupt? If the relative sparing of the aged were due to the greater proportion of survivors in the older age groups who had been immunized by previous attack, why was there no uniform change in the proportions between 1890 and June, 1918? As the Registrar-General said, "It may be doubted whether so sudden and so complete a change of age incidence can be paralleled in the history of any other disease." Finding no answer to these conundrums, many have given up the problem in disgust. Colonel Gill seems to treat these difficulties rather lightly.

It is thus assumed that prior to the onset of the summer epidemic in 1918 old and debilitated persons who would otherwise have constituted the most susceptible age group, had been removed by death and that a considerable proportion of the population belonging to the higher age groups had acquired as the result of the epidemics during the years 1890-1918 a relatively high degree of immunity.

If these surmises be correct it is clear that they afford an explanation of the relatively high death rate amongst the aged in the pandemic of 1890 and of the relatively low death rate in the higher age groups during the years 1918 and 1919.

The italics in the last-quoted paragraph are ours. We think the devil's advocate would say, first, that there is really no evidence that the surmises are correct, and, secondly, that even if they were they would leave the remarkable discontinuity as perplexing as ever. If Colonel Gill were to retort that no man could say precisely when the equilibrium of the immunity "quantum" and the infection "quantum" would be upset, the devil's advocate would reply that that was only a slightly involved way of saying that epidemics in fact happen, and perhaps even quote the author's remark early in his treatise that "it would not serve any useful purpose to recount the innumerable forms assumed by the deistic theory of the origin of epidemics."

It is, however, neither fair to the author nor to his subject to stress what, in the reviewer's opinion, are weaknesses. We are, indeed, of opinion that Colonel Gill's standard of what constitutes an adequate theoretical description, or—in ordinary language—explanation is not very high and that he sometimes pays himself in words, but we are also of opinion that his book deserves to be widely studied, and is worthy of the traditions of his service.

M. G.

RECENT ADVANCES IN SURGERY

MR. W. H. OGILVIE has undertaken a difficult task, but has discharged it so well that *Recent Advances in Surgery*² is worth its place in any surgeon's library. The author has been assisted by Mr. J. F. Carter Blaine, Mr. T. P. Kilner, Mr. Grant Massie, and Mr. V. E. Lloyd, who contribute chapters which add greatly to the value and interest of the book. Mr. Ogilvie, in his preface, points out the difficulties of deciding what is recent, what is an advance, and even what is surgery, but he and his collaborators have struck a very happy mean, and are to be congratulated on the judicial attitude adopted throughout the book. If circumstances seem to justify a clear verdict, or if "non proven" sums up the present state of knowledge, they are equally ready to say so. The book is well illustrated with photographs and diagrams and a good list of references follows each chapter.

Tannic acid in the treatment of burns is a notable absentee, and we hope to see some mention of this very remarkable advance in the next edition. Perhaps, too, there should be some mention of radium as a serious competitor to excision of the carcinomatous rectum. None the less, omissions are few, and the range of the book is

¹ *The Genesis of Epidemics*. By Clifford Alablin Gill, Lieutenant Colonel, I.M.S. D.P.H. London: Baillière Tindall and Cox, 1928. (Med. Soc. pp. xxvi + 550. Illustrated. 21s. net.)

² *Recent Advances in Surgery*. By W. H. Ogilvie, M.D., M.Ch., Oxon., F.R.C.S. Eng. London: J. and A. Churchill, 1928. (5½ x 8½ pp. vii + 451. 106 figures. 15s.)

Interest is well sustained, and it is pleasant to encounter an occasional aphorism "A muscle cannot recover if it has too much work, and will never recover if it has none," is the signpost to salvation for poliomyelitis. "Every operation for [gastric and duodenal] ulcers appears to be a success until it is found out" is equally refreshing. American mass statistics have been freely used, and the unrivalled numbers of the Mayo Clinic are often helpful in arriving at conclusions. None the less it is cheering to see so many British references, and to realize that this country is contributing its full quota to surgical advance.

Mr Ogilvie rightly emphasizes the present tendency towards simplification and standardization of operations. He agrees with Sir Berkeley Mowbray that operative ingenuity has reached its peak. Lichsen said much the same thing, and time proved him wrong. Mr Ogilvie, however, with commendable caution, adds the proviso, "except possibly in the direction of the transplantation of organs." His section on rejuvenation tonics on this subject—in fact, there are few surgical subjects upon which he does not touch. There are many old friends in the book, and some new acquaintances to us, such as Sever's and Kienboch's diseases. If we are not to be allowed to invent new operations, we can still look forward to discovering plenty of diseases and giving them euphonious names.

ACIDOSIS AND ALKALOSIS

THE French workers LADDE and NERVEUX have recently published, under the title of *Acidosis and Alkalosis*,² a book which summarizes their own clinical and laboratory experiences of these conditions, as well as those of other workers. This publication will undoubtedly serve as a very useful book of reference. Its interest is mainly centred in the discussion of the ketosis of diabetes, but many other pathological experimental conditions are dealt with, and a large bibliography appears at the end of each chapter. One very important feature of the book is the care and detail with which the necessary laboratory methods are described. It is possible to learn from it, for instance, methods for determining the pH of the blood, the alkali reserve of the blood, the tension of alveolar CO₂, and the amounts of ammonia, of acids, and of acetone bodies excreted in the urine. The physiological mechanisms by which the acid base equilibrium of the blood is kept at the normal level, and the significance of departures from this normal equilibrium, are very clearly discussed. When attempting to follow the author's theories regarding the causes of the onset of ketosis in diabetes the reader may feel handicapped by the fact that the distinction between the terms "acidosis" and "ketosis" is not kept sufficiently clear. Indeed, no mention is made of the fact that, whereas acidosis does not necessarily involve ketosis, alkalosis can lead to definite ketosis, and also to carbohydrate intolerance and diminished oxidation of carbohydrate, thus imitating the conditions found in diabetes. The omission of these facts leaves the section of the book which deals with alkalosis incomplete, and the general discussions of problems of diabetes would perhaps be more helpful if the authors had them more definitely in mind.

THE EXTRA OCULAR MUSCLES

ANOTHER addition has been made to the already large literature on the subject of the movements of the eyes and squint by Professor FETTER of Pennsylvania in a handbook on *The Extra-ocular Muscles*.³ The volume is essentially clinical in character and professes to limit itself to practical problems rather than theoretical discussions. It is divided into five parts. The first of these deals with the anatomy of the ocular muscles and the physiology of their associated movements. This is handled in the orthodox fashion, in the anatomical section the researches

of Whitnall on the orbit have been utilized to good advantage and the physiology is described with care and discrimination, a sound balance being struck between the classical views and the large amount of recent work which has been directed to this complex problem. The second part, dealing with heterophoria, suffers somewhat from confusion introduced by the large number of clinical tests described, a fault which is universal in every book on the subject. The elaboration of new methods for detecting and estimating errors of muscle balance offers a fertile field for the exploitation of clinical ingenuity, and the matter has been certainly overdone. The teaching in these pages, however, is sound on the whole, though many would consider it impracticable to advise the use of prisms so powerful as is recommended, the employment of 10 prism dioptres in hyperphoria, for example, seems excessive, and likely to give rise to more discomfort than relief. In this defect of muscle balance, also, the correction of small deviations of less than 15 prism dioptres is probably rather more important and beneficial in its effects than is suggested here. In the third part, which deals with squint, a very great deal of importance is attached to the part played by the "fusion faculty" in the determination of concomitant strabismus, and in discussing the operative treatment of this condition it is noteworthy that, while advancements or resections are favoured before other procedures, tenotomy is banned and recession is advised. Even so, however, it is thought advisable to hold recession in reserve as a supplementary procedure in all cases to increase the effect of single or bilateral advancements. The fourth part deals with paralytic squint, and there is appended a note on nystagmus.

STERILITY IN WOMEN

THE successful treatment of *Sterility in Women*,⁴ according to Dr SIDNEY FORSDIKE, "confers greater happiness upon the people concerned than any other form of surgical procedure." The newer methods of investigation and treatment by inflating the uterine tubes, and by x-ray examination after the injection of opaque material such as lipiodol, have tempted him to give his experience of them. The methods he employs both for inflation and for injection of lipiodol, are described in detail, and illustrated by seventeen plates of x-ray photographs, or what he calls "hystero-grams." His results are given and discussed fairly and judiciously. The new methods were devised primarily for diagnosis, but Rubin claimed 10 per cent of pregnancies following inflation, and Forsdike finds his own results show this figure to be rather an under-estimate than an over-estimate. In 100 cases inflated 15 pregnancies followed, and out of 67 in which lipiodol was injected the tubes were found patent in 41, and of these 14 (that is, 34 per cent) became pregnant. The difficulty in deciding between *post hoc* and *propter hoc* in these cases is acknowledged, and no explanation is attempted as to why the injection of an opaque substance such as lipiodol to enable an x-ray plate to be taken should also increase the chances of pregnancy—but there are the figures. Chapters are included on the causes of sterility and on other methods of examination and treatment, and the book can be recommended as giving a reasonable account of the clinical features of sterility in women under present-day conditions. The clinical are much better than the scientific portions, in which there are many errors—for example, that ovulation and menstruation occur about the same time, and that fibroids cause sterility when "the fibrous tissue is so widely prevalent in the uterine wall as to produce a condition of atrophy of the endometrium." There are also loose statements on the cessation of "ovarian function," by which term apparently "ovulation" alone is implied. Another defect is the number of generalizations that are either incorrect or at least impossible to prove. Far too many conditions are mentioned as "invariably the cause of" or "invariably associated with" sterility or dysmenorrhoea or other symptoms. Finally, the book is marred by careless use of words, so that the meaning is often to seek.

NOTES ON BOOKS

The work on hospital hygiene* by Drs. LOUIS MARTIN and R. DUJARRIC DE LA RIVIERE of the Institut Pasteur forms the eighth volume of the system of hygiene edited by Martin and Brouardel. The opening pages consist of a historical introduction, and the remainder of the work is divided into five parts, to each of which a bibliography is appended. In the first the writers discuss the organization of a hospital in detail, including the site arrangement of the wards and other buildings, water supply, drainage system, ventilation, heating, lighting, disinfection, furniture, and disposal of staff. The second part is devoted to a consideration of special hospitals (including those for children), hospitals for acute infectious disease, almshouses and mental hospitals. In the third part the admission to hospital of social diseases such as tuberculosis, syphilis, alcoholism, and cancer is discussed. The fourth part is concerned with the hospital staff, in which are included medical nursing, pharmaceutical and administrative units with a full consideration of the training of nurses, and in the fifth part hospital administration in foreign countries (Germany, Austria, and the United States) is described. The text is freely interspersed with plans and photographs of hospitals in France and other countries. The work, though mainly based on the study of French hospitals, will be of interest to all those concerned in the management of hospitals, such as medical superintendents, medical officers of health, and visiting committees.

The seventh edition of *Aids to Gynaecology*† has been edited by Dr. R. E. TOTTENHAM, professor of obstetrics and gynaecology in the University of Hong Kong. To give the general principles of a large subject, such as the diseases peculiar to women in a hundred pages or so is a matter of extreme difficulty, but the author of this small book may well be congratulated on the success obtained. That a seventh edition has been called for is evidence of its appreciation by those who find benefit from studying notes of the important gynaecological conditions. Nurses and junior students will find Professor Tottenham's edition very useful, as each chapter is written with an entire absence of frills and unnecessary matter.

Professor FELIX KLEWITZ's monograph on bronchial asthma,‡ which forms the latest instalment of the system of medical practice edited by L. R. GROTE A. FROMME and K. WARNEKROS, contains a concise, clear, and up-to-date description of the nature, diagnosis and treatment of asthma, based on the writer's personal experience in East Prussia and a study of the literature.

Recent Advances in Organic Chemistry,§ by Dr. A. W. STEWART, is a work in two volumes, in which are collated and connected various achievements of research in different branches of organic chemistry. It has for its object the establishment of data for reference by those engaged in research, as well as the presentation of those data in a form readily accessible to students. The previous editions have kept the author's presentation level with historical developments. In this, the fifth edition, much new matter is included corresponding with more recent advances, the first volume containing matter suitable for third year students and the second for students engaged in post graduate work and research. Notable progress has been made among the alkaloids, the anthocyanins and the synthesis and cleavage of proteins. The author has not confined his treatment to a favoured section but has covered the wide field of organic chemistry very thoroughly. One feature of his work that can hardly be overestimated is that he has risen high above the level of an annotator. The description is in the form of connected narrative, and is alive with a spirit of enthusiasm for the elucidation of theoretical views and a ready aptitude for intuitive deduction. In this manner are discussed not only those subjects which have attracted attention by reason of their novelty, but a great number of others which add to the understanding of organic compounds. One chapter is occupied in the discussion of some theories of the natural synthesis of vital products, another deals with some applications of electrometry to organic chemistry, and the final chapter discusses certain unsolved problems of long standing.

A book on *Incompatibility in Prescriptions*¶ has been prepared by S. K. MUKHERJI which will be found very useful both to prescribers and dispensers. It presents a general discussion of the causes of incompatibility, citing cases from actual experience in great abundance, and it affords, through the medium of a tabulated list and an index, readily accessible information on questions that may arise in practice.

The Phenomenology of Acts of Choice|| by Miss HONORIA M. WELLS and *An Experimental Study of the Mental Processes Involved in Judgment*|| by Mr. B. P. STEVANOVIC, embody the results of researches carried out by the authors in the Psychological Laboratory at King's College, London, and presented as theses for the degree of Ph.D. There is therefore a certain family resemblance between them. Both represent painstaking work in prolonged series of ingeniously devised experiments which are described in detail. They are now published as Nos. 11 and 12 of the series of monographs issued in connexion with the *British Journal of Psychology*.

PREPARATIONS AND APPLIANCES

BONE SHEARS

MR. H. MORRISTON DAVIES, M.Ch. (Ruthin), communicates particulars of a new bone shears. He writes: "The principal point about these bone forceps is that they have a sheen action which

enables one to cut the rib, leaving a perfectly clean uncrushed surface, and using the minimum of force. The character of the forceps enables the blade to be inserted under the rib, even when the ribs are close together, with the minimum of risk of

damaging other parts. The blades can be slid along the ribs under the tissues, and so cut even at a distance, if necessary, from the wound. To accomplish this a right handed and a left handed pair are necessary. The whole design gives maximum strength with minimum weight.

The Holborn Surgical Instrument Company, Ltd., are the makers of these bone shears.

AN IMPROVED CAECAL CLAMP

MR. JOHN TAYLOR, Ch.M. (Dundee), writes: "I have designed a special clamp for the operation of caecostomy as a first stage procedure in acute obstruction due to malignant disease of the proximal colon. It is a modified form of Hartmann's clamp, with a deep curve. The object of the clamp is to exclude temporarily from the increased colon pressure a portion of caecum large enough to permit the insertion of a large Pezzer catheter without any leakage taking place. When the bowel is grasped with the usual type of deeply curved clamp the points of the

blades always gape, and leakage and soiling are almost inevitable, the Hartmann points overcome this difficulty. Before applying the clamp the caecal contents are slowly expressed into the colon, the Pezzer or similar type of catheter is then introduced into the flaccid caecum in the same manner as for the bladder, and the purse string suture is tightened and tied. The clamp is then slowly eased in order to prevent tearing by a sudden return of colon pressure. The caecal wall is stitched to the parietal peritoneum and the catheter is connected up to a suitable form of container. With this technique the catheter does not tend to work its way out. A smaller but similar type of clamp is useful in anastomotic gall bladder operations. The clamps were made for me by Mr. Charles F. Thackray, Park Street, Leeds.

VOLKMANN'S ISCHAEMIC CONTRACTURE.

THERE are certain complications of common injuries which do not receive the attention they deserve because their occurrence seems to cast a reflection upon the skill and competence of the surgeon who treated the case. Ischaemic contracture is a notable instance of this. It was probably the notoriety of a recent medico legal case which led to ischaemic contracture being chosen for a discussion in the Section of Orthopaedics at the Cardiff Meeting of the British Medical Association, and it is fortunate that Sir Robert Jones was willing to review the whole subject in an address (printed in our opening pages to day) which will for many years to come remain as a surgical classic.

The condition has been observed in both the upper and lower limbs, but, as it is in connexion with fractures round the elbow joint that the great majority of cases have occurred, attention was confined to this class of injury. The onset of ischaemia is within a few hours up to forty eight hours from the time of the accident or from the time at which treatment is begun. This onset is marked by pain and swelling of the hand and forearm, a blue or dusky colour of the skin, and loss of movements in the fingers. Unless the tension is relieved blisters or blebs form under the epidermis. These changes it is generally recognized, are due to interference with the circulation, and this explanation is confirmed by the absence or feebleness of the pulse while the blueness and oedema are evidence of venous obstruction.

Ever since Richard von Volkmann of Leipzig first described the condition in 1875 the essential nature of the paralysis and its dependence upon obstructed circulation in the muscles have been admitted on clinical evidence. Within recent years this has been confirmed experimentally by the work of the American observers Brooks and Jepson, who showed that venous as well as arterial obstruction was required to cause the vital damage to the muscle fibres. The actual circumstances which bring about this circulatory obstruction are generally one or other of the following: the pressure of tight bandages over splints and position of the limb which produces great tension, either extreme flexion or extreme tension of the elbow, or the simple effusion of blood under the deep fascia. Unfortunately the first of these causal factors has been the only one taught or recognized and in consequence, the idea has become prevalent that if tight bandaging and splinting are avoided then ischaemia cannot occur. Sir Robert Jones points out that the degree of flexion required to maintain a fracture in good position is really only of moderate amount—that is to say the position maintained by fixing the wrist to the neck by the cuff and collar method. But the term 'acute flexion' has somehow crept in, and in recent years the majority of cases of ischaemic contracture have resulted from the adoption of this position. Thus the most widely used English manual of surgical practice teaches that after supracondylar fracture the arm should be fixed in front of the chest with the elbow fully flexed.¹ The fact has been observed that in the normal arm the pulse at the wrist

can be stopped by pressing the hand against the shoulder, and further, that if a few cubic centimetres of water are injected into the antecubital space a considerably less degree of forcible flexion will then cause cessation of the pulse. Many cases have been noted and published in which ischaemic contracture followed injury to the soft parts without any fracture, these include certain haemophilic patients in whom a subfascial haematoma had developed in the region of the elbow or forearm.²

Treatment of Volkmann's ischaemic contracture has been the subject of many suggestions, but in this country it is formally held that patient perseverance in the method advocated by Sir Robert Jones will always bring about considerable improvement. Unfortunately this requires a long period of time, and great determination on the part of patient, and manipulator. There seems to be no short cut to recovery, and such operations as excision of a portion of the forearm bones or multiple tendon lengthening have rightly been abandoned. The sliding of the common tendon from the internal epicondyle, or a downward displacement of the condyle itself, is a recent suggestion the adoption of which has given encouraging results, but even this will not preclude the necessity for prolonged splinting and stretching of the finger tendons. In regard to the treatment of the condition in its acute stage, there is good reason to advocate the plan of incision through the skin and deep fascia in order to relieve the tension on the vessels. Leriche of Strasbourg for some years past has advocated and practised the operation of periarterial sympathectomy of the brachial artery with a view to bringing about a vasomotor dilatation in the tissues of the forearm.

Sir Robert Jones closes his paper with some sound advice to young surgeons and general practitioners in dealing with fractures of the elbow-joint. He lays stress upon the importance of obtaining an x-ray photograph, and about this there can be no dissentient opinion. But recent medico legal cases have shown that x-ray plates themselves may be used in support of a charge of negligence. This makes it all the more essential that every practitioner should belong to a medical defence society, but however much that may protect him from pecuniary loss, it will not save him from heart-breaking litigation. We wish it were possible to end on a more cheerful note, but such, we fear, will be the conclusion reached also by the Medical Society of London on November 12th, when a discussion on the medico legal aspects of fractures is to be opened by Professor Hey Groves and Dr James Neal.

ACTINOTHERAPY THE NEED FOR CONTROL

THE papers by Professor W. E. Dixon and Dr C. B. Heald read before the Section of Radiology and Physiotherapeutics at the Annual Meeting of the British Medical Association at Cardiff, and published this week (p. 642 and p. 644), bring effectively into focus the knowledge that has been gained from the widespread and increasing application of various forms of radiation in physiotherapy, and emphasize the danger that may accrue to the public, and, indeed, to the medical profession, from the exploitation of these therapeutic devices at the hands of untrained unqualified persons.

The enthusiasm with which the introduction of

¹ Ross and Carless. *A Manual of Surgery* (twelfth edition) p. 57.

² Hey Groves. The Surgical Aspects of Haemophilia with especial reference to Two Cases of Volkmann's Contracture Resulting from this Disease. *British Medical Journal* March 16th 1907 p. 611.

actinotherapy into general medical practice was at first greeted has given place to an equally regrettable scepticism. When there are doubts as to whether a therapeutic device can do any good there is the danger of an accessory doubt as to whether it can do anything at all—even harm. This is a pity for although actinotherapy cannot fulfil all the claims made for it by some of its more sanguine exponents, there exists a definite set of conditions in which its employment is indicated and though in skilled hands it may provide a treatment of the first importance improperly used it may do the gravest mischief. When statements appear to the effect that 'all cases of skin diseases are benefited,' or that 'all cases of rheumatism acute or chronic, neuritis, sciatica, will be benefited, if not cured,' we can only conclude that some people are easily satisfied. The general experience is that many cases of skin disease are unaffected by this treatment—some are even aggravated, and it is by no means yet determined whether the beneficial results produced in some cases of rheumatoid arthritis, neuritis and sciatica are not due merely to a counter-irritation of the same order as that produced by a mustard plaster. There can be no doubt, however, that actinotherapy properly applied is an important agent in the amelioration of rickets and surgical tuberculosis—often indeed, in these conditions producing complete cure and that certain neurological conditions anaemias and skin diseases though not cured, are usually benefited by this treatment. Among diseases of the nervous system in which amelioration of symptoms has been claimed are acute anterior poliomyelitis (in which actinotherapy is stated to limit the spread of the paralysis and to cut short the period of disablement), Bell's palsy in its early stages, the root pains of tabes dorsalis, and herpes zoster. On the other hand, it is equally important to recognize that to patients suffering from pulmonary tuberculosis, arterio sclerosis, chronic nephritis, quiescent appendicitis, and various forms of neurosis the application of ultra violet radiation may do definite and irretrievable harm. Early phthisis is of special importance in this connection. It is generally realized that ultra violet therapy is contraindicated in active febrile cases. Frequently overlooked, however, is the fact that a focus of early or of latent phthisis may flare up into activity as the result of the incautious administration of ultra violet rays. But it is just the person in whom one of these conditions may be present—the slightly run down asthenic person—who is most likely to turn to ultra violet radiotherapy for the sake of its tonic effects. The difficulties moreover, do not end with the selection of the right kind of case. A proportion of patients—the number has been given as 4 per cent—suffer almost immediate ill effect from general irradiation. Their main symptoms, which include malaise, headache, pain in the back, vomiting, conjunctival irritation, and occasionally diarrhoea were described by Dr Paige Arnold in a contribution to the *British Medical Journal* published on February 13th 1926 (p. 304). There is furthermore, the risk of producing light allergy from over-dosage, due according to Professor Dixon, to the absorption of altered skin proteins into the patient's circulation.

Clearly a treatment capable of so much good and of so much harm should be administered only by those with the requisite knowledge and skill. In point of fact, it has largely fallen into the hands of unqualified practitioners incapable of applying it with due regard to the idiosyncrasies of the patient or the condition from which he may be suffering and unmindful of the problems of technique and dosage—persons ignorant of

electricity, ignorant of the physiological effects of the different types of radiation, and ignorant of medicine.

In view of this serious situation the Representative Body of the Association, on July 20th at Cardiff, strongly recommended that immediate steps should be taken to place this form of treatment under the control of the medical profession, and indicated the general lines along which such control should be exercised. Thus the resolution expressed the opinion that an approved register should be made of persons fitted to administer this form of treatment, that suitable courses should be organized for the training of those who wish to qualify for inclusion in this register that a condition for inclusion should be abstention from the treatment of any patient except under the general supervision of a registered medical practitioner, and that patients requiring electrical or radiation treatment should be referred only to persons thus registered. As it stands, the resolution neither defines the authority which should be made responsible for giving practical effect to the opinions expressed nor does it indicate the method by which such an authority might fulfil its duties. This lack of definition was not unintentional. Having stated its opinion in general the Representative Meeting naturally felt that the Council of the Association was the proper body to review in detail the means by which the aims set out in the resolution would best be achieved.

The matter now rests in the hands of the Council, which has already appointed a special committee, composed of members of the Science and Medical Political Committees, to define the details of this policy. We look forward to an early and a unanimous report by those best qualified to express an opinion on the licence that should be allowed to the administration of this form of treatment. The sooner this is embodied in definite and enforceable regulations, the sooner will the general public gain the greatest measure of benefit and (what may be of even more importance) the greatest measure of protection.

THE HARVEY FILM

THE cinematograph film showing the series of experiments carried out by Harvey in formulating his proof of the circulation of the blood, which was prepared by Dr H. H. Dale and Sir Thomas Lewis for the Royal College of Physicians of London, and was exhibited at the Harvey tercentenary celebration last May, will be shown, by permission of the Royal Society of Medicine, in the Barnes Hall at 1, Wimpole Street, W., on Tuesday, October 30th, at 5 p.m. In compliance with the injunction of the Home Office that the film should be shown only to scientific audiences, admission will be limited to medical practitioners and students of medicine, who may obtain tickets, bearing their own names and not transferable, by calling personally either at the issue room of the library of the Royal Society of Medicine or at the office of the Royal College of Physicians in Pall Mall East. As the seating accommodation is limited early application is advised.

'DEATH FROM NATURAL CAUSES

THE *Revue Medicale de la Suisse Romande* of September 10th contains an article by Drs F. Naville and Ed. Rosset on difficulties and errors in the diagnosis of the cause of death. The authors are attached to the Medico-Legal Institute of Geneva to which bodies are sent for examination in cases of doubt. It appears that to some of these bodies the Swiss doctor attaches a diagnosis of startling precision, suggesting powers of divination, in others he contents himself with the provisional statement, "Death from natural causes." Drs Naville and Rosset

have examined the reports on these "natural death" cases made in the Institute during the last two years, and they record some remarkable findings. Thus the Geneva police stopped the funeral procession of a man stated to have died of tuberculous haemoptysis, he had been murdered by a stab in the back with a knife. A woman certified to have died from gastric ulcer had been the victim of criminal abortion, preceded by the vomiting of pregnancy. Another woman was found dead in bed, it was supposed from natural causes, but when the nun who sat up with the corpse the following night was also found dead in the morning, a little investigation showed that both women had died of carbon monoxide poisoning. The necessity for completely stripping and examining dead bodies is illustrated by cases in which razor wounds of the throat were concealed by scarves round the neck, and stiletto punctures by a pendulous breast. The authors describe the case of a healthy young shepherd of 28, certified as dying from natural causes. Yet the autopsy showed a veritable museum of injuries: fractures of the skull, three ribs, and a clavicle, traumatic haemorrhages in the brain, the liver, and the kidney. In another body, "dead from natural causes," with no lesion exteriorly, there was fracture of the skull with a large cerebral haemorrhage, the result of a fall in the course of a dispute with a companion. The authors of this article remark on the difficulties and damage that may arise from failure to ascertain correctly the cause of death. To conclude hastily that a drowned person has committed suicide may prejudice the relatives in the matter of insurance. The drowning may have resulted from an attack of epilepsy, an accidental fall, a cerebral haemorrhage, cardiac syncope, vertigo due to ear diseases, or other fortuitous causes. And it seems that in Switzerland failure in investigating the cause of death may bring disaster upon the doctor, as in the case of the practitioner who was called to a body on a mountain road, and through negligence failed to discover a penetrating wound. His conclusion of "death from natural causes" led to his being deprived of the right to practise medicine. The authors recognize that it is human to err, and they sympathize with the doctor who must try to be exact in his diagnosis while surrounded by policemen, relatives, friends, and neighbours, who harass him with contradictory statements. But they hope that their remarks on "deaths described as natural" may serve to remind their professional brethren of the need for as careful an investigation as possible of the causes of death.

THE PROFESSION OF MESSAGE.

AMONG the allings ancillary to medicine that of the masseur is of particular importance to the medical practitioner. The actual technical details of treatment by massage and medical gymnastics and such electrical methods as are carried out by the masseur often require a high degree of skill and experience, and it is of the utmost importance that the medical man should be able to rely confidently upon his assistant who works under his direction. The Chartered Society of Massage and Medical Gymnastics, since it obtained a new charter in 1920, has steadily extended its activities. It represents now the only recognized portal of entrance to this profession, and its registered members number 6,721, established in practice in practically every town in the British Isles. Of this number 6,321 are massesseurs and 400 are masseurs. The members pledge themselves to work only under the direction of a medical practitioner, and in this respect differ from the still numerous unregistered, and often unqualified, members of their calling, who can and do treat anyone coming to them for advice without reference to or instruction from a doctor. The Chartered Society has recently completed an inspection

of all the training schools recognized by it, and the inspectors have presented a full and detailed report to the council, in which the accommodation, the course of instruction, and the opportunities for gaining clinical experience are commented upon and criticized. With this inspection, and the steady raising of the standard of examination, the level of the work of the massage profession in this country has certainly reached a very high standard. Unfortunately doctors very often fail to recognize the difference between a trained and registered masseur or masseuse and one who is imperfectly trained or untrained—one who has, moreover, never signed on undertaking to work only under medical supervision. During the past year the Chartered Society obtained from the Privy Council permission for its members to use the term 'chartered masseur or masseuse.' If medical practitioners will take care that those whom they employ to treat their patients have the right to this title, they may feel confident that they are placing the treatment of their patients in the hands of properly qualified people, who will only carry out the instructions given to them after a medical diagnosis has been made. A congress of the Society was held from October 3rd to 6th in the Great Hall of the British Medical Association House. The lectures and demonstrations given each day were numerous and attended. At the Annual General Meeting, over which Sir Cooper Perry presided, it was reported that during the past year twenty-three examinations had been held and 315 conjoint certificates (that is, in massage and medical gymnastics) had been granted, together with 54 in massage alone, 31 in medical gymnastics alone, and 242 in medical electricity. Sir Cooper Perry deplored the fact that few of the medical schools took the opportunity of teaching their students the value of massage, the reason being, of course, the overcrowded state of the medical curriculum. The meeting approved a proposal to provide for proxy voting at general meetings of the Society. This has been brought forward by the council in view of the setting up of new ethical by-laws, in the framing of which and their application to any given case it is desired that as many members as possible should have a voice. Following the annual meeting Sir Arthur Keith delivered an interesting address on the conflict between theory and practice in medicine, which is reported on another page.

CONFESSIONS OF AN AMATEUR PHYSICIAN

'It goes without saying that every white man is a doctor and healer of all conceivable ills—in the eyes of unsophisticated natives.' With these words Brigadier-General H. H. Austin begins his very readable reminiscences of amateur doctoring in some of the waste or savage places of Africa, which appeared in the September *Cornhill*. He disclaims all title to special knowledge and makes in defence of a possible charge of unqualified practice the unanswerable plea of necessity, as well as policy, which compels the white man in authority in remote places to support as best he may the reputation so touchingly thrust upon him by the ignorant savage. Masters of merchant ships which do not carry surgeons have to shoulder a like responsibility, although in these days of steam and wireless they find more opportunities of getting skilled help than of yore. Many of General Austin's medical experiences were gained among the Swahilis of East Africa, whose own vigorous methods of counter-irritation by means of the actual cautery are said to be sometimes efficacious. He comments on the blunt sensibilities of these people, as shown in their calm submission of their persons to the knives of their comrades, when huge thorns or other intrusive substances have to be excised. Small-pox was rising near Lake Victoria Nyanza, and once again vaccination, at the hands of General Austin and his staff, proved

its efficiency—so far as a scanty stock of lymph allowed. All the officers of the party and the forty Pathans who had accompanied them from India were vaccinated before starting, and all escaped infection, although freely exposed to it. The mortality among the negroes is stated as "appreciable." On a later visit to British East Africa it was found that a nuisance from which the country had formerly been free had appeared. This was the "chigoe" or jigger (*Pulex penetrans*), so well known in West Africa and some other tropical places. General Austin describes the well-known methods of treatment of the deposited ova, and observes that the great carnivore, as well as men, suffer from these pests. In 1899 again he found himself in command of a survey party on the borders of Abyssinia without a medical officer, and once more he had to become an amateur physician and surgeon. Luckily this country was free from jiggers, and the health of the party was good, only one death—apparently from an "acute abdomen"—occurring, but the amateur physician himself narrowly escaped increasing the death roll, for he suffered for ten days or more from frequent vomiting, for which he took opium tablets. Whether this treatment was efficacious or not, who shall say? The end crowned the work. Other travellers at other times in those regions seem to have suffered from similar symptoms. Ipecacuanha and hot fomentations appear to have saved the life of the young wife of an important Abyssinian. He has little good to tell of the Gallas and Abyssinians with whom he came in contact, who were ready enough to seek his medical aid, but whose gratitude was certainly confined to expectations of future favours. It seems that luckily he was not called in to assist in any cases of difficult labour, in which he would have had to rely on the *vis medicatrix naturae* only. On yet another expedition in East Africa General Austin had the advantage of the services of Surgeon John Garner of the Egyptian Administration, to whose memory—he died two years later—he pays a warm tribute. The party suffered much from various hardships and diseases, General Austin himself having nearly succumbed to a virulent attack of scurvy, during which the sight of one eye was permanently damaged by a haemorrhage into the retina—a complication as distressing as it is unusual. In concluding this pleasant record of often unpleasant experiences, General Austin tells us with disarming candour that his object in seeking publication is to restore to the members of his own family their lost confidence in his therapeutic skill.

MALARIA COMMISSION OF THE LEAGUE OF NATIONS

A REPORT in pamphlet form has been published of the conference held in June at Geneva of the Malaria Commission of the Health Organization of the League of Nations. Three subcommissions were appointed to consider special aspects of the problem of malaria control, and the conclusions reached were subsequently approved by a full session of the Commission. The first subcommission, which reviewed antimalarial methods, emphasized the necessity of there being a permanent Government organization in each country to study local conditions, since each antimalarial method is affected by the prevailing social and economic conditions, and has, therefore, no fixed and universal coefficient of necessity, efficacy and cost. It is added that imitation in antimalarial work is dangerous, and methods likely to lead to discouraging results should be avoided. The subcommission did not favour the utilization of all available methods of control in the same locality at the same time, but advised the employment only of those methods which, with the means available, could be brought above a standard termed the "minimum effective degree of perfection." It reported that, whatever other means might be employed in malarial localities, it was essential in the

first place to treat the sick, and that the good results of early diagnosis and efficient treatment were more apparent in the reduction of the severity of the disease than in the reduction of its incidence. The execution of the measures must reach a sufficiently high degree of efficiency—"minimum effective degree of perfection"—before its effect on incidence could become appreciable. The second subcommission discussed certain aspects of the epidemiology of malaria and necessary future studies, the long list of suggestions for research serving to show how many points still remain obscure in the wide field of malaria. The third subcommission considered the use of quinine in malaria. It endorsed the method whereby quinine is continued after an attack for four to six weeks in daily doses of 1 gram, but advised that in the latter half of this period no quinine should be given for three to four days in each week. This subcommission declared definitely that the first step to take in malarial localities is to arrange for treatment by quinine.

ETIOLOGY OF HIRSCHSPRUNG'S DISEASE.

ANY contribution towards the elucidation of the underlying pathology of Hirschsprung's disease is to be welcomed, since in the hands of even the most skilful surgeon the outlook in the majority of cases of this condition is anything but bright. In the August issue of the *Archives of Disease in Childhood* Dr J. A. Munro Cameron supplies a complete and most instructive description of the pathology of a case of Hirschsprung's disease. The portion of the colon above the pelvic rectal sphincter showed gross enlargement of the bowel with much hypertrophy of the circular muscular fibres. Viewed through the pelvic-rectal sphincter, the muscle itself seemed normal, but in the intermuscular plexus of nerve cells the ganglia were replaced by inflammatory cells, and only an occasional nerve cell, shrunken and degenerated, was to be seen. Dr Cameron recently published in the *Archives* an account of cardiospasm, showing that the underlying pathology was a degeneration of Auerbach's plexus, and in the present article he compares this with the pathology of Hirschsprung's disease. They are indeed similar in every way. Since Hirschsprung's disease is in a large proportion of cases congenital, he considers that the meconium of the newborn infant must have become infected, and have passed on the infection to the bowel wall, with destruction of the intermuscular nerve plexus. Stasis occurs above this site, and the bowel, in attempting to pass on its unaccustomed burden, hypertrophies, especially in the circular muscular layer. The author offers the suggestion that dilatation treatment should succeed in Hirschsprung's disease as it does in cardiospasm, since the pathology of both is identical. His paper is illustrated with two admirable photomicrographs.

THE Harveian Oration before the Royal College of Physicians of London will be delivered on Thursday next, October 18th (St. Luke's Day), by Sir Humphry Rolleston, Bt. K. C. B., Regius Professor of Physic in the University of Cambridge, who has taken as his subject "Cardio-vascular disease since Harvey's day." The Oration will be given at 4 p.m. in the theatre of the College, Pall Mall East.

IN connexion with the forthcoming by-election of two direct representatives for England and Wales on the General Medical Council, we publish in the *Supplement* this week the joint address issued to the electorate by Dr J. W. Bone of Luton and Dr E. K. Le Fleming of Wimborne, the candidates chosen by the Representative Body for support by the British Medical Association.

Opening of the Winter Session.

CHARING CROSS HOSPITAL.

ADDRESS BY DR T WATTS EDEN

THE inaugural address at the Charing Cross Hospital Medical School was delivered on October 4th by Dr T WATTS EDEN, who also distributed the prizes and certificates. One student (Miss L. S. Hobbs) secured the prize in medicine, in surgery, in practical midwifery, and in ophthalmology, together with certificates in gynaecology and in pathology and bacteriology, as well as winning the "Llewellyn" scholarship. Of the thirty-five prizes and certificates, seventeen went to women students. The dean, Dr F. H. YOUNG, in his annual report, mentioned that the council had decided that no further women students should be accepted at Charing Cross. The school had been confronted with the possibility of remaining the only co-educational school in London, and it was felt that this meant that it would become predominantly a women's medical school. During the past year eighteen men and twenty-two women had qualified from the school.

Dr WATTS EDEN said that for the practitioner of medicine the sense of being at school continued throughout the whole of his career. Perhaps this was true of all professions, but it was peculiarly true of medicine. The character of the lessons altered, but the pundits of the medical school were only exchanged for the stern mentor of responsibility which made the conscientious man his own hard taskmaster. Soon after graduation the student made the discovery that there were quite a number of things he did not know, this was disturbing, because most young graduates thought that all they had to do was to go out into the world and exercise their profound knowledge for the good of humanity. He remembered that on the day when he was capped a Bachelor of Medicine he believed himself to possess a great body of exact knowledge which would carry him through everything, but since that date his confidence in what he knew had been gradually crumbling. A further discovery which the young practitioner of medicine would make was that even his teachers and occasionally his textbooks had been wrong. What was called medical science—never an exact body of knowledge—was always undergoing revision. The knowledge held to-day might in ten years' time prove to be wrong, possibly so far wrong as to be dangerous in its application. Consequently the practitioner had to be an assiduous reader, keeping himself familiar with the advances of medicine, a responsibility lightly felt at the time but getting heavier year by year. Another discovery very soon made by the general practitioner was that the patients whom he treated did not get well with the swiftness and swiftness that they should, he came to realize that his failure in some cases arose not from perversity of the patient but from his own lack of technical knowledge, skill, and judgement. The public could not expect any one practitioner to know everything, but they had a right to look for efficiency, and this depended upon the most trifling details. Failure sometimes arose from inability to establish relations of confidence and sympathy with the patient. The most successful doctors he himself had known had not been those who knew most, but those who understood their patients best, had the gift of sympathy, and could inspire confidence. Another disturbing thing which the young practitioner would experience was that a love of quackery was ingrained in the community. Quackery had always been in existence in one form or another, but in recent times it had assumed some strange forms, and was not unknown even within the ranks of the medical profession itself. Quackery appealed to some members of the profession either because they were born with a "quack mind" and drifted into medicine by mistake, or because they were ready to take any short cut which offered pecuniary reward. Medical men were passing through a difficult time. The public was more critical and perhaps more suspicious than formerly, and most people nowadays imagined themselves

to possess a certain amount of medical knowledge. They lived on familiar terms with their various organs and functions. They were not prepared to accept medical men as arbiters of their destiny, and any assumption of the pontifical attitude by the profession was received with contempt. Certain societies, with the assistance of the popular press, were disseminating the impression that orthodox medical practice was all wrong, and that in the columns of daily newspapers was wisdom chiefly to be found. The public had been told that good health followed upon the eating of a rather indigestible form of bread, drinking paraffin regularly, and paying frequent visits to the lavatory. In conclusion, Dr EDEN urged upon those who would make up the rank and file of the profession the maintenance of a sound judgement and a high standard of efficiency. Sometimes the practitioner would be pressed by a patient, reinforced by the patient's family, to take a course contrary to his own judgement, but his clear responsibility was to do the right thing and to wait until the right moment came to do it. Even if the patient in consequence left him for someone more pliable the consciousness of having done the right thing would give him an inward satisfaction which nothing else could afford.

Annual Dinner

The annual dinner of past and present students was held at Gatti's Restaurant, London, on the evening of the same day, with Sir HERBERT WATERHOUSE, consulting surgeon to the hospital, in the chair.

Proposing the toast of "The Hospital and Medical School," Sir Herbert Waterhouse referred with regret to the resignation of Mr. Charles Gibbs, senior surgeon to the hospital, and of Dr. Feuton from his position of dean of the Medical School. He expressed the great debt of gratitude the hospital and school owed to Mr. Gibbs, in his view the finest surgical teacher in London, and to Dr. Feuton, who, having filled with distinction the office of dean during war and post-war years, resigned after serving in this capacity for eleven years. After welcoming Mr. Crook as assistant surgeon, and Dr. Vines, late director of medical studies at Cambridge, as pathologist, he congratulated Dr. Young on his succession to the office of dean, and Dr. Banister to that of vice-dean. He then referred in graceful terms to the guests of the evening—Air Vice-Marshal Munro and Mr. Ingleby Oddie—and extended a warm welcome to Mr. Verity, chairman of the Hospital Committee, and Mr. Philip Inman, secretary-superintendent. Reviewing the progress made in the last quarter of a century, he gave an account of the great debt the hospital and its school owed to Mr. Verity. Twenty-five years ago, he said, there was no money to meet liabilities, there was even a danger of closing the hospital. One member of the council stirred up everyone by his enthusiasm, that was Mr. Verity. It was his genius for organization that not only wiped out a debt of £140,000, but secured £100,000 for extending the hospital and taking over and rebuilding the premises of the Royal Westminster Ophthalmic Hospital. Especially he thanked Mr. Inman for the invaluable work he had done in the difficult financial situation of the past year. Mr. VERITY said that the sceptical response to his early enthusiasms reminded him of a stained glass window best described under the title of "Joseph telling his dreams to his somewhat irritated brethren." Charing Cross Hospital had, he was proud to say, digested the carcass it had picked up at the end of the street finances, thanks to Mr. Inman, were running smoothly, and the Pathological Institute was doing work of immense public importance. The reconstruction of the new premises would involve not only drastic improvement of the out-patient and casualty departments, but the initiation of measures to secure paying wards for the hospital and a new hostel for the nurses. He hoped the State would not lay a cold and interfering hand on the great work that was going on in the voluntary hospitals. Dr. F. H. YOUNG, after referring to the stability of the medical school (which,

thanks to Mr Inman, was better than solvent, though in March it owed no less than £4,500), made a statement on the decision no longer to admit women students to the Medical School. The reason that had actuated the committee was that the six other co-educational hospitals were closing their doors to women, and if Charing Cross proceeded as the only co-educational hospital in five years it would cease to be that, but become a women's hospital altogether. He was proud to say that representative women from the hospital had expressed, as their only regret at the decision, the fear that it might involve their being shut out from the hospital for which they had so much affection. Following this decision the entries of male students for the coming term were larger than they had been for long past. Mr C JENNINGS MARSHALL, proposing the health of the chairman, referred to Sir Herbert Waterhouse's irrepressible boyish enthusiasm, which would never let him grow up. Sir Horbort did not retire from professional life, as during the past three years he had served with distinction as president of the Medical Defence Union, and had just been re-elected for a fourth year. In the course of a witty reply, the chairman appealed to all present to join the Medical Defence Union. During the evening a delightful musical entertainment was provided by Dr Taylor-Harris (an old Charing Cross student) and his friends, and Miss Elise Steels, there was also a conjuring performance by Mr Horbert Collins.

KING'S COLLEGE HOSPITAL

ADDRESS BY PROFESSOR ERNEST BARKER

At the opening of the session at King's College Hospital, London, on October 3rd, the chair was taken by Sir W. WATSON CHEYNE. The report by the dean, Dr WILLOUGHBY LYLE, showed that at the present time there were in the school 227 ordinary students, 63 of whom were engaged in preliminary and intermediate courses at King's College and elsewhere, while 164 were undertaking their final studies at the hospital. In addition there were 65 qualified men and women who were at the school preparing for higher degrees and diplomas. Sympathetic reference was made to the loss sustained recently by both the hospital and school in the death of Lord Hambleden.

The inaugural address was delivered by Professor ERNEST BARKER, lately principal of King's College, London, and now professor of political science in the University of Cambridge. Professor Barker gave a brilliant address, marred only at one point when, in speaking of the "syndicalist" tendency of doctors, he referred to the "British Medical Council" (*sic*) as the most highly organized of all British guilds. He took for his text the Greek word *physis*, which, he said, like many other words, especially those used by medical practitioners, had a very long history. This word originally meant "growth," but became widened until, like the Latin word *natura*, it came to include all nature, inanimate as well as animate. It was from this word that "physio" and "physician" were derived. "Physio" was the study of the processes of nature, and "physician" a man concerned with those processes, partly by understanding them, which was his science, and partly by conducting them, which was his art. The first to separate medicine out of philosophy was Hippocrates. He took out of the whole body of curious inquiry into *physis* at large the one subject of the physical processes of the human body, and said that that was enough for him.

The orator proceeded to compare Hippocrates and Aristotle, dwelling especially on the work of Hippocrates entitled *Airs, Waters, and Places*. Hippocrates was no determinist, and he acknowledged frankly that human institutions and laws might remedy the effects which climate, left to itself, would always produce. The same spirit of eager scientific inquiry appeared in Aristotle, who was possibly indebted to the school of Cos. The spirit of scientific research as exemplified in Aristotle consisted in the observation of the attributes of whatever was studied, experiments and dissection of specimens, and the endeavour to find some explanation of those attributes. The members

of the school of Hippocrates were adepts in observation. In the field of experiment they did not achieve much, their strength lay in simple observation of cases whereby they sought to explain the origin of disease and to apply the appropriate remedy. All this, Professor Barker believed, affected Aristotle, both directly in his biological studies and indirectly in his study of politics. Aristotle was himself the son of a court physician, and might have helped his father, medicine being a hereditary calling amongst the Greeks. He had a mind peculiarly fitted for zoological study, and declared that the study of every kind of animal should be ventured on without distaste. That was the temper of the physician also, and Aristotle followed the physician in his eager observation of structure of parts and organs and in the use of dissection. In Aristotle's *Politics* there were traces of the doctor, or at any rate of the zoologist. Just as the doctors of Cos observed their cases and drew their conclusions, just as Aristotle the zoologist, influenced by them, recorded his observations and made his attempts at explanation and theory, so Aristotle the political philosopher constructed on the basis of the observation of 158 constitutions a theory of politics. He divided those constitutions into normal and perverted, the latter being greedy, tyrannical, and selfish oligarchies. The fifth book of the *Politics*, which was devoted to these perversions, had been called Aristotle's study of the pathology of the State. He also sought to prescribe remedies, his main prescription being "moderate diet." He pointed out, for example, that the over-exercise of power brought about its downfall.

The Aims of a thousand years ago combined medicine and philosophy, the two were signally associated also in the school of Cordova, and in the court of the Roman emperor Frederick II. The sixteenth century was a great age for the philosophic physician, the names of Servetus, who died at Geneva for his faith, of the Italian physicians Eustachius and Fallopius, after both of whom parts of the human anatomy were named of Harvey, and many others came to mind. Two other English doctors were to be commemorated in the same connexion. One was Thomas Linaeus, a Greek scholar, the founder of two lectureships—"one, in gratitude, for Oxford, and the other, in pity, for Cambridge." The other was Thomas Sydenham, friend of John Locke the philosopher, and sometimes called the English Hippocrates.

In conclusion, Professor Barker advised the student to learn to clothe his physics with some philosophy and some general wisdom. There was no nobler figure than that of the wise doctor, who maintained breadth of interest and general capacity of mind. He recalled in this connexion Sir Thomas Browne, and also a modern one whom he happened himself to have known—Sir William Osler. Gratitude was due also for the physician's humanity, which was wrapped up with his skill, Hippocrates said, "If you have love for your fellow men you will have also love for your art."

A vote of thanks to the orator was proposed and seconded by Professor G. F. STILL and Sir CHARLTON BRISCOE.

THE MIDDLESEX HOSPITAL

ANNUAL DINNER

The annual dinner of the Middlesex Hospital was held at the Savoy Hotel on October 2nd. PAUL ARTHUR CORNWORTHY, chairman of the hospital, presiding. After the loyal toasts had been duly honoured, Prince Arthur proposed the toast of "Prosperity to the Middlesex Hospital and its Medical School." The urgent necessity of reconstructing the hospital created by the dangerous condition of the old building had, he said, been faced with courage and confidence. Apparent disaster had served as an incentive not merely to reconstruct but to develop in such a way that the hospital and its school should become factors more powerful than ever in the prevention and treatment of disease. His close association with the institution for four and a half years had taught him that hospitals were not merely institutions for tending the sick, but were in reality the guardians of national health. In his view it was vital that everyone in the country should

he taught to value properly the need for trial and experiment, in both the clinic and laboratory, in relation to every aspect of disease. The public must realize that the voluntary hospitals laboured unceasingly towards the end of preventing disease, and that its responsibility to these institutions was governed as much by self-interest as by charitable feeling. Reviewing progress made, Prince Arthur said that the building of the new west wing was nearing completion, the central boiler-house was completed, the Courtauld Institute of Biochemistry was full of determined workers with a set purpose before them, and the first section of the new nurses' home, the gift of an anonymous donor, would be completed within twelve months. The whole history of the voluntary hospital system contained, he believed, no finer record than theirs, no higher inspiration, no greater encouragement to anticipate the final success of their contribution in promoting the cause of health and happiness. The scheme of development included the provision of a block for paying patients. The governors held that the voluntary hospitals should be available not for one class only, but other classes should be brought within reach of their benefits, and they had determined that such an extension should be made. They could, however, obtain the necessary capital only from two sources—from those who would directly benefit and from those with wealth and goodwill. The outlook had been gloomy but their persistent courage did not go unrewarded. He was proud to say that a friend of the hospital had put at their disposal the munificent gift of £125,000 which would enable them to realize their great ambitions. The new service would now become an integral part of the hospital's functions and would constitute an example of the intelligent use of opportunity for the good of as many as possible. He was confident that the admiration and gratitude they felt for the donor would find responsive echo in the hearts and minds of those who would benefit directly and of the whole country. Mr S A COURTALD, responding, said that the generous gift ensured the successful completion of the hospital's great reconstruction scheme. He had had convincing personal evidence of the real value of the hospital's pathological institute to the country practitioner lacking the facilities for the laboratory investigations essential to diagnosis. Mr ERIC PEARCE GOULD, dean of the Medical School, in the course of a most amusing speech, modestly referred to the tremendous work that had been done by everybody except himself. He announced that this was probably the last annual dinner at which he would be present in his function as dean of the Medical School. Dr G H DOBNEY also replied. Dr HENRY MACCONAIG proposed "The Guests" in graceful terms, and Surgeon Vice-Admiral GASKELL, Medical Director-General, R.N., and Dr E W AINLEY WALKER, dean of the Faculty of Medicine at Oxford University, replied. Admiral Gaskell made a plea for the sending of the best type of man into the medical service of the Royal Navy. He was very glad to say that during the past year some of the best recruits to his service had come from the Middlesex Hospital. Dr AINLEY WALKER deplored the tendency in medical education to multiply a smattering in specialities. However much the student of medicine was given small doses of this, that, or the other specialization, he would find, after half a dozen years of practice, that knowledge had advanced and methods changed. Only one thing was never out of date and that was a trained mind. The function of medical education was the training of the mind of the medical student. Mr ROBERT L HUYTER, proposing the health of "The Chairman" announced that Lord Woolvington, who made such a generous gift to the Middlesex Hospital, was also the donor of £50,000 towards the fund for the restoration of St George's Chapel, Windsor. After his health had been drunk with musical honours the CHAIRMAN responded with a delightful speech, in which he said that what had struck him above all in the Middlesex Hospital was the great pride that all those connected with it took in the fact that they were Middlesex men. At the conclusion of the dinner, students, past-students, and their guests adjourned to a reception room for conversation and the renewal of old associations.

ST MARY'S HOSPITAL

OLD STUDENTS' DINNER

THE annual dinner of the past and present students of St Mary's Hospital School was held on October 5th at the Trocadero Restaurant, with Dr E G MOON of Broadstairs in the chair, supported by Sir John Rose Bradford, President of the Royal College of Physicians, Surgeon Vice-Admiral Gaskell, Air Vice-Marshal Munro, and senior members of the hospital staff. The attendance of students of various periods was larger than at any previous dinner.

Proposing the toast of "St Mary's Hospital and Medical School" the Chairman paid a warm tribute to the high traditions characteristic of both. With many anecdotes he illustrated the progress of the hospital in the past, making special reference to the building of the Mary Stanford Wing, and to Sir John Broadbent. Lieut-Colonel H E VEREY, D.S.O., deputy chairman of the hospital board, replied to the toast, and expressed deep regret at the absence of Mr A R PRIDEAUX, who, after a long connexion with the hospital, including eleven years of chairmanship of the board, had been obliged to resign for reasons of health. Mention was also made of the great loss sustained by the death of Mr Maynard Smith. Colonel Verey reported that the hospital had ended the last year with a financial balance on the right side, but it had to be remembered that the new buildings, including wards and operating theatres, would impose an additional annual expenditure of £7,500. He commented on the necessity of building a new medical school, inoculation department, and nurses' home; this would make available the accommodation for paying patients which he regarded as one of the greatest needs of the present time. In the three essential departments of the work of a great hospital—namely, research, medical tuition, and the care of patients—St Mary's had won a very high reputation in the world. The toast was also responded to by Dr C M WILSON, dean of the Medical School, who referred to the part taken by co-education in providing for the increasingly heavy expenditure since the war. The entry of students continued to be satisfactory, but there was room for still further increase in this respect. Towards the sum of £160,000 required for the new school buildings about £100,000 was still wanted; this would be easily obtained if the fine example set in collecting money during the past year by the Pathological Institute, led by Sir Almoth Wright and Dr John Matthews, was followed. Dr Wilson added that the virtue of any medical school was to be found in the quality of the students who went out from it to take up work in all parts of the Empire; he paid a high tribute to the character of the present students, which justified confident hopes of the standard being maintained.

Mr V WARREN LOW, senior surgeon to St Mary's Hospital, proposed the toast of health and continued prosperity to the Chairman. In a warmly appreciative speech he referred briefly to Dr Moon's many-sided ability, as a sportsman he had been distinguished in football, cricket, and golf. He was also a great-hearted man, and a skilful and highly respected general practitioner, to whom very many people brought their troubles for solution.

THE PHARMACEUTICAL SOCIETY

ANNIVERSARY DINNER

THE Pharmaceutical Society of Great Britain held a dinner at the Hotel Victoria, London, on October 31st, in celebration of the sixtieth anniversary of the passing of the Pharmacy Act of 1868. Mr HERBERT SKINNER, president of the society, was in the chair.

Sir GREGORY FOSTER, Vice-Chancellor of the University of London, proposed the toast of "The Society and its Benevolent Fund," tracing the evolution of the modern pharmacist from the old-time alchemist and apothecary. How these people became pharmacists, he said, was not quite clear, but the change of name really was significant. He then referred to the educational work of the society, saying that he was specially interested in the school in its connexion with the University.

of London. No modern development has been more important than the association of pharmacy with the universities. The country was realizing that if it were to be properly served in the various activities of life it must be by trained men and women, who were only to be found among those who had that fundamental education on which the universities insisted before the candidates entered for degrees. There were now in Britain twenty five approved schools of pharmacy, three being connected with the universities of London, Glasgow, and Manchester. Their school in connexion with the University of London was growing steadily, and the men and women coming up for that course were improving in quality and calibre every year.

The PRESIDENT, in reply, said the Act of 1868 made confusion worse confounded, but it had a very warm corner in the heart of every pharmacist. The seed of goodness it contained was that for the first time it united chemists and druggists with the Pharmaceutical Society, the keystone of the Act was unity in pharmacy, and that was the greatest thing for which they could give it credit. It was the first Act that recognized their authority as the sole dispensers and distributors of poisons, and it was not until 1911 that they had the National Health Insurance Act, which made them dispensers to the nation, under that Act nearly sixty million prescriptions were dispensed annually. The Act of 1868 made the society the authority for carrying out the poisons law of the country, and for sixty years they had done so faithfully for the protection of the public only. He hoped they would go forward with this work for the benefit of the public, that, in pharmacy as in medicine, was the only test that they were doing their job.

Mr E T NEATHERCOAT proposed the toast of The Houses of Parliament, remarking that in future legislation Parliament should very carefully consider the policy and practice of the pharmaceutical leaders of the last sixty years. In responding, Sir GEOFFREY BUTLER, M.P., commented on the growth of a new interest in the nation's health. In this matter, he said, the Houses of Parliament were powerless alone, it was only in collaboration with bodies such as their society that permanent progress could be made.

Replying to the toast of The Guests, proposed by Mr L MONROE PARRI, vice president of the society, Sir ARTHUR ROBINSON, Secretary of the Ministry of Health, said it was a curious thing that in this country when one wanted to govern a profession well one asked it to govern itself. In his own time this practice had been extended to nurses and dentists, and others were asking for similar privileges. There was room for doubt as to this in some cases, but none in the case of the pharmacists. Sir Arthur Robinson then referred to the services rendered by the society and its laboratory in the administration of the Therapeutic Substances Act. He endorsed what had been said regarding the high level of performance in the work done under the National Health Insurance Act, saying that they should be proud of the way in which that public service was performed.

Among those present were Sir Wilfred Sugden, M.P., Sir W H Willcox, Sir Henry Jackson, Surgeon Vice Admiral A Gaskell, Medical Director General R N. Mr Colin Smith, Deputy Clerk of the Privy Council, Professor W E Dixon, Professor F T G Hobday, Professor H G Greenish, Dr J P Share Jones, Mr R B Pilcheg, Mr G Stubbs, Deputy Government Chemist, Dr Alfred Cox, Medical Secretary of the British Medical Association, and Dr P Haas.

OPENING OF THE SCHOOL OF PHARMACY

The inaugural address at the opening of the eighty seventh session of the School of Pharmacy was given on the afternoon of the same day in the hall of the society by Mr REGINALD BENNETT, chairman of the British Pharmaceutical Conference, who spoke on pharmacy as a career. He said that pharmacy had not yet acquired the material recognition that was its due. It was only by united efforts in educating public opinion that its claims could be brought home to the uninitiated. In aiming at the enhancement of status there was a constant demand for improvement in matters educational, technical, and ethical. The course that pharmacists should pursue was to cultivate assiduously the scientific side of pharmacy, in the promotion of pharmaceutical research, and in keeping pharmacy abreast of advances in biochemistry, pharmacology, and kindred subjects. Only by giving first place to the professional side would it be possible to maintain and to enhance the esteem in which pharmacists were held by their fellow men.

ROYAL VETERINARY COLLEGE

At the opening of the new session at the Royal Veterinary College on October 2nd, Sir Arthur Weigall, who presided, said that the college was going through a period of difficulty. Governments had in the past shirked their responsibilities in regard to the veterinary profession. A departmental committee had, however, been appointed to inquire into the future of the college, and there was thus a possibility of the responsibilities being placed on the shoulders that ought to bear them. Sir Merrick Burrell said the fact that the college was in its present position was not altogether the fault of the governors. In 1919 they made an appeal to the authorities for help, but it was shelved. The seriousness of the present position could not be exaggerated, and if the governors did then duty from the purely financial point of view they would close the college to avoid bankruptcy. But they could not do that, education must go on. He hoped it would be the departmental committee's duty to ask for everything it thought necessary. Professor F T G Hobday, principal of the college, said that for the present session there was one of the highest entries they had had for many years. They desired a minimum of £250,000, and some of the money was on the way.

OLYMPIA MOTOR SHOW.

MORE POINTS FOR MEDICAL MEN

[FROM OUR MOTORING CORRESPONDENT]

DISCUSSION of the relative merits of different makes of car is particularly popular during the period of the annual motor show, which is now proceeding at Olympia and will continue until Saturday, October 20th. In point of fact choice of car nowadays is determined far more by the means of the purchaser, the presence or absence of this, that, or the other fitting, and the individual's aesthetic preference for certain types of bodywork, than by any objective variations in the mechanical efficiency of the cars on the market. The improvement in motor engineering has been such that, generally speaking, all cars may now be depended upon to give efficient service over a long period, if only attention is given to the ordinary problems of lubrication and care and adjustment of machinery.

Price not the Only Factor

Medical practitioners require cars that, despite daily use in all weathers, will maintain the good appearance of their external and internal bodywork for a long period. A little reflection will show that the lowest priced car is not necessarily cheapest in the end. The popular priced cars, while there is no question of their being excellent value for money, must in some directions fall short of those costing more. Examples that come to mind are the quality of the paintwork and of the upholstery. Artificial leather, which in some instances is adopted for the latter, though meeting well enough the requirements of a section of motor users, has not, nor is it claimed to have, the wearing qualities of real leather. It is therefore suggested that doctors looking round for a new car should not let the question of price be the only determining factor in their final decision.

Standardization of Controls

We appear to be still far from achieving any degree of uniformity in the control gear of cars. It is therefore gratifying to note that the Standardization Committee of the Society of Motor Manufacturers and Traders is taking steps to bring about some standardization in this direction. As examples of unnecessary varying practice one may cite accelerator pedals, which on some cars are to the right of the brake pedal and on others between the clutch and brake pedals, the former position being recommended. The position and direction of movement of steering wheel ignition levers, and of throttle control levers, are at present also determined by the individual designers. It is proposed that ignition levers should always be to the left and move upwards for advance, and that throttle levers should be on the right and open on the upward movement. Thus the levers, when nearest the driver, would be in the

retarded and closed positions. Similarly, a standard form is recommended for the different speed positions of the change speed lever for three- and four-speed gearboxes.

The Lighting of Cars

In the section of accessory exhibits—a section rich in devices and of contrivances claimed to enable the light of motoring—are contained a large number of anti-dazzle devices and of contrivances claimed to enable the light of lamps to penetrate through the foggiest of atmospheres. One of the most useful novelties to which attention may be drawn is the new anti-dazzle "dip and switch" reflector shown by Joseph Lucas, Ltd. About a year ago this firm introduced a dipping reflector which has been widely adopted. In the new device the headlight reflector on the near side is arranged to dip and at the same time automatically to turn to the left and light up the near side of the road. Simultaneously the off side headlight is automatically switched off and remains out during the whole period of dipping. Thus, in addition to avoiding the dazzling of oncoming drivers, will be found useful, it is claimed, when fogs and mists are encountered.

Last week reference was made to the importance of giving due weight to reliable lighting when choosing a new car. The batteries must be regarded as important as the dynamo and starter themselves. A number of firms now specialize in making these for use in motor vehicles, among them being Vandervell's, Oldham's, Lucas's, and the Chloride Electric Storage Company. The latter are the makers of the well known Exide batteries, for which a long life is claimed. The firm rightly point out that against the cost of a battery must be reckoned the degree of service it renders—another instance of the importance of not over-stressing the price factor.

Unsplinterable Glass

A noteworthy feature of the show is the increasing attention now being devoted to the manufacture of unsplinterable glass. In view of the great increase in motor traffic and the consequent greater risk of accident, there is no question of the desirability of its employment for wind-screens and for the windows of covered cars. On most cars it is at present only fitted at an extra charge, but most doctors using their cars in traffic would consider this extra charge worth paying. The pioneer of safety glass was the Triplex Company, but there are now several other varieties available.

Some Notable New Cars

The outstanding feature of the show is the large number of six- and eight-cylinder cars, the prices of which are no more than had to be paid a few years ago for the better-class four-cylinder vehicles. Moreover, a tour of the exhibition reveals the fact that, despite the American and foreign bid for the car made in this country, British manufacturers have nothing to learn from them in the art of motor construction, and that it is possible to find British cars meeting every possible requirement.

One of the surprises of the exhibition is the new six-cylinder car shown by Armstrong-Siddeley Motors, Ltd., which is listed at £250, either as an open two or four-seater, and at £275 as a four-seater fabric saloon. The new chassis is similar to the firm's 15 h.p. car introduced a year ago, and has a side-valve engine with a bore and stroke of 56 by 84 mm. A single-plate clutch conveys the drive to a centrally controlled three-speed gearbox, which is mounted on the forward end of the propeller shaft torque tube. The wheel base of the vehicle is 8 ft 9 in., and the track 4 ft., semi-elliptic springs are used all round, and the steel disc wheels are shod with 27 by 44 in. balloon pneumatic tyres. The equipment of the vehicle is very lavish, and includes speedometer, clock, petrol gauge, and unsplinterable glass in the windscreen. The firm are also continuing to manufacture their 14-h.p. four-cylinder, and 15-h.p., 20 h.p., and 30 h.p. six-cylinder cars. Attention is drawn, moreover, to this firm's display of what is known as the "self-changing" four-speed gearbox, reference to which was made last week, and which can now be fitted at an extra cost to the 20-h.p. and 30 h.p. cars. It may also be mentioned that the Armstrong-Siddeley vehicles are

provided with a central lubrication system, the operation of a pedal forcing a supply of grease to all parts of the mechanism requiring it.

The Popular Morris Vehicles

There are probably no more popular cars in this country than those which bear the name Morris. Considerable interest attaches, therefore, to the 1929 programme of the Morris Company. It has been known for some time that the firm had decided to put on the market a smaller edition of their Cowley car, and so to enter the field which has so far been practically monopolized by the Austin seven. It is claimed for the new Morris minor, although its prices have been fixed at the same level as the Austin, that it is intended less as a competitor of the latter than as an effort to popularize the use of motor vehicles among the section of the public to whom such prices would represent an outside limit. The new vehicle has already been so widely described that it need here be only mentioned that it is fitted with a four-cylinder engine with a tax rating of 8-h.p., and that it has a petrol consumption of fifty miles to the gallon, a three-speed gearbox, wire wheels with 26 by 3½ in. pneumatic tyres, brakes on all four wheels as well as one behind the gearbox, dynamo lighting and starting, and bumpers both fore and aft. The new car is being supplied both as an open four-seater and as a saloon, the wheel base being 6 ft 6 in. and the overall length 10 ft 2 in.

The improvements in the Morris-Cowley range of 11 h.p. cars, the saloon of which is now priced at £190, comprise a lower chassis, improved springs, dipping headlight reflectors, an electric horn, bumpers, and better bodywork. Similar improvements have been made in the 14/28-h.p. Morris-Oxford cars, the prices of which range from £200 to £277 10s for the saloon de luxe. There is also a 16/40-h.p. four-cylinder Oxford at prices from £295 to £330, while for the 1929 season the Morris Company are arranging to devote more attention to the 17.7-h.p. six-cylinder car, which was introduced last year, and is now being built in coupe and saloon forms at prices varying from £305 to £390. As it is impossible to show a full range of the Morris cars in the limited space available at Olympia, the firm of Stewart and Arden, Ltd., as sole London distributors, closely associated with the Morris productions, are holding a special exhibition during the period of the motor show both at their showrooms at 103, New Bond Street, W., and at their service and repairs establishment at Acton, W.3, which latter is claimed to be the largest of its kind in the world.

1 Citroën Light Six

Users of Citroën cars—which are a very popular type with many doctors—will be interested in examining the new light six-cylinder model, the engine of which has a bore and stroke of 72 by 100 mm. Ignition is by coil and distributor, and the Solex carburettor is supplied with petrol from a tank at the rear through the medium of an Autovac. Steering is of the worm and wheel type, with provision for adjustment. Semi-elliptic springing is employed all round and shock absorbers are fitted. The final drive is by spiral bevel gear, the rear axle incorporating oil baffles of a particularly effective kind. The car has a very attractive appearance, with high, narrow radiator, well-placed lamps, and smooth-lined all-steel bodywork. As a four-door saloon it is priced at £295. A feature of the whole range of Citroën cars, which includes in addition to the new "six," 13/30-h.p. and 12/24-h.p. four-cylinder models, is a wider track, enabling wider bodies to be fitted. By dispensing with body cross-members and mounting direct on the frame, the bodies, in addition to being 2 in. wider, are lower, with a pleasing absence of valance.

The Austin Range

The policy of the Austin Motor Company is to embody any improvements which appear to be desirable in their various models as and when opportunities occur, and not to keep them back for the purpose of introducing new cars at the annual exhibition. In this they are following the long adopted policy of such soundly established motor concerns as Rolls-Royce. Although, therefore, the show discloses nothing sensational in connexion with the Austin

cars, one finds a number of detail changes that have been made since the last exhibition. For example, in the ever-popular "Seven," larger headlamps, mounted forward and fitted with separate dimmer bulbs, are now used, the dash has also been provided with ventilators, while an improvement of some importance is that the brake drums are now secured to the wheel hubs. The Austin 12-h p four-cylinder, the 16-h p six-cylinder, and the 20-h p "fours" and "sixes" have similarly, at various periods during the past year, been subjected to slight alterations to afford users greater convenience and simpler service. The petrol tank, for instance, can now be filled without disturbing the driver, the filler having been moved to a more accessible position, and a petrol depth gauge is now fitted on the dash.

In addition to these chassis changes, various new body models have been added to the Austin range, the "seven" coupe at £135 being a notable example. Others include the Burnham saloon and four-window fabric saloon on the 12-h p chassis, and an improved saloon on the 16-h p six-cylinder chassis. There is no more popular car among doctors than the Austin 12-h p. The prices of this have been reduced, and now range from £245 to £315. For an additional £50 users have now the option of the Austin 16-h p "light six," which bids fair to become as popular in the market for which it caters as the "seven" in its own.

Humber and Standard Cars

The chief feature at the Humber Company's stand is a new 16/50-h p six-cylinder car the engine of which has the inlet valves inclined in the head with the exhaust valves in the usual position at the side. The Humber 9/28-h p four-cylinder car has undergone considerable improvement, while in all models one notices a redesigned radiator, dipping headlights, and a stop signal combined with the tail light.

The Standard Motor Company, Ltd., are retaining their 9-h p, 14/28-h p, and 18/42-h p four-cylinder cars, and in addition are introducing a new 15-h p six-cylinder vehicle. The "fours" are unaltered in chassis design, but the 9-h p fabric saloon has been much improved in appearance. A new model 9-h p has also been introduced, this is known as the "Teignmouth" saloon, the special features of which are separate bucket seats and the "Stanlite" roof, which can be opened or closed as desired. The chassis of the new car is identical with the other 9-h p models, with the exception of a 7 in. longer wheel base, this being 8 ft 3 in. The new 15-h p six-cylinder car is an extremely interesting model, and has been designed to give a high top gear performance. The engine, which has a bore and stroke of 63.5 by 102 mm, is provided with a seven-bearing crank shaft. A unit construction four-speed gearbox is used, and semi-elliptical springs fitted with rebound leaves are employed front and rear. The cars on view include an attractive fabric saloon known as the "Exmouth," listed at £325.

More Coventry-built Cars

A car attracting considerable attention is that shown by the Alvis Car and Engineering Co., Ltd.,—a 12/75-h p four-cylinder vehicle, notable in that the engine power is transmitted to the front wheels instead of as usual to the rear. At present the car is mainly designed for sports use, but it may be that sooner or later the front drive will become more general. The Alvis Company are also showing their 14/75-h p four-cylinder cars, which, although on more orthodox lines, are well worth examining. The chassis on which an Alvis light saloon body is mounted is particularly attractive.

The most striking feature of the Hillman Motor Car Company's programme for the coming season is the introduction of a 197-h p car with a "straight-eight" engine, to be marketed as a saloon at £485. The specification includes unsplinterable glass, dipping headlight reflectors, wire wheels, servo-operated brakes, etc. The Hillman 14-h p four-cylinder cars, which have proved very successful during the past year, are being made with over two

hundred detail improvements in the chassis. Of these the more important are a 4 in. wider track, lower build with same ground clearance, deeper and more handsome radiator, electrically controlled dipping headlamps, and increased strength throughout. It is noticeable that the saloons are not only wider, but, while permitting the same head room, 3 in. lower than formerly. In the bodies, which have steel panelling, valances have been eliminated.

During the past few years Riley (Coventry), Ltd., have come rapidly to the front as builders of speedy but reliable cars. A special feature of the Riley "nine" is that it has four speeds, and that the third speed gearwheels are in constant mesh and claimed to be just as quiet as the top gear. Among the body designs is a new "Biarritz" saloon, in which special attention has been paid to the construction and mounting in order to minimize interior noises. The new Riley 14-h p six-cylinder car may be described as a larger edition of the "nine." Its R A C rating of 13.5-h p is no clue to the power development capabilities of the engine, which is fitted with overhead valves. In addition to a touring car there are two varieties of saloons supplied on the new 14-h p chassis at £495 and £525 respectively.

A notable alteration in the plans of Vauxhall Motors, Ltd., is that they have ceased to manufacture their 30/98-h p and sleeve-valve-engined cars, in order to concentrate on the 20/60-h p six-cylinder model introduced a year ago. Into this they have incorporated a number of improvements. By a slight increase in engine size, and by the redesigning of the head, the intake manifold, the cam shaft, and the silencer, increased power to the extent of about 25 per cent is claimed. A choice of nine designs of open and closed bodywork at prices ranging from £495 to £695 is available for the new chassis.

Having commenced this week's review of the show with what may be termed the popular range of car exhibits, it may be well to close with a reference to the exclusive vehicles of the Rolls-Royce Company, whose exhibit is always the centre of interest and admiration at Olympia. The various models displayed this year are no exception to the rule. The 40/50-h p car is represented, among others, by a six-cylinder "Phantom" chassis with a Barker enclosed limousine body seating six persons. The price of the complete vehicle is £3,037. The smaller 20-h p six-cylinder Rolls-Royce is also on view, one, priced at £2,042, being fitted with a Thripp and Maberly enclosed drive limousine body painted claret and black. Needless to say, the cars, being built to a quality rather than a price standard, are magnificent examples of the modern art of car construction.

Next week it is hoped to review other cars exhibited at Olympia, and also to draw attention to some of the more interesting accessory exhibits in the galleries.

SEGREGATION OF THE MENTALLY DEFICIENT

THE Mental Deficiency Act of 1913 is in itself beneficent. By its provisions the congenitally weak-minded members of the community may be segregated, cared for, and scientifically treated and trained. By its means they can be delivered from the squalor and wretchedness of their home lives, as often as not with mentally defective parents, and be placed in sheltered surroundings, where they may be enabled to lead happy lives, often of surprising usefulness. Nor are the benefits of their segregation confined to themselves. The community is relieved from much of the burden of poverty, crime, and disease which are directly traceable to this mentally defective population. It is therefore of the utmost importance that the intentions of the Legislature should be fully realized in the administration of this Act. The present position is far from satisfactory, and it must be a matter of grave concern to all who have the best interests of the country at heart.

The Commissioners of the Board of Control¹ report that urgent cases are frequently brought to their notice in which prompt action is necessary in the interest both of the individual and the community, and that no accommodation is available. The lack of accommodation becomes every year more serious, and the Commissioners fear that unless a great effort is made in the immediate future it may become impossible to administer the most important sections of the Act. To appreciate aright the present difficulties which are being encountered in the functioning of the Mental Deficiency Act, it is necessary to recall its main provisions and the conditions which brought these into being.

A long and arduous campaign by enthusiastic social workers who were profoundly dissatisfied with the neglect of the weak-minded members of the community, and the attendant growth of all manner of crime, resulted, after repeated representations to Parliament, in the appointment in 1904 of the Royal Commission on the Feeble-Minded. After a searching inquiry, extending over four years, this Commission presented a unanimous report, in which it was stated that the evidence compelled the conclusion that there were numbers of mentally defective persons whose training was neglected, no sufficient control was exercised over them, and their wayward and irresponsible lives were productive of crime and misery. The Commission was convinced that much misery and injury resulted to these persons and to others, and that useless expenditure occurred, wasteful both to the community and to the individual families. As a result of the labours of this Commission the Mental Deficiency Act came into being, and was in full operation on April 1st, 1914. It accepted the principle of unity of control which the Commission had recommended, but by dividing the authority mainly between the Board of Control and the Board of Education—this latter body being responsible for feeble-minded children between the ages of 7 and 16—and by setting up a highly complicated procedure, it cannot be said to have brought about the co-ordination of activities which the Commission had envisaged.

Unfortunately, the advent of the war made it impossible for either the Mental Deficiency Act or the Elementary Education (Defective and Epileptic Children) Act to come into complete operation. Rigid economy had to be enforced, and it became necessary to postpone many schemes for the accommodation of mentally defective persons, and to restrict the operation of the Act to such cases as required immediate control. Local authorities, however, were urged to proceed with their duties of obtaining all necessary information with regard to the number and condition of defectives within their own areas, so that everything might be in readiness for the full functioning of the Act when circumstances permitted. This duty of detecting and certifying defective persons had none the less been undertaken by only a few of the local authorities, but it was hoped that when the armistice came all such deficiencies would be remedied. Unfortunately, the Board of Control was again under the necessity of postponing provision for defectives owing to the still urgent need for economy. Many questioned seriously, as did the Board of Control, the wisdom of a policy of retrenchment with regard to expenditure on mental defectives at a time when owing to widespread unemployment, the feeble-minded must necessarily be the first to be thrown out of work and into all manner of temptation. Very slow progress was made in the years which followed. Still, in 1921, Government instructions retarded development of work under the Mental Deficiency Act, again the county and county borough councils had to be informed that the programme for 1922 must be "restricted to the execution of commitments already made and which cannot be postponed." During this period, as since, the work of the Voluntary Central Association for the Mentally Defective admirably supplemented the necessarily limited operations under the statute.

Notwithstanding repeated representations to local authorities to assume their duties under the Act, the Board of

Control was still in 1925 writing that "the subject which calls for the most serious attention is the want of accommodation for all types of defectives," and was pointing out that hundreds of urgent cases had been, and were being, discovered for which no vacancies in existing institutions were available. According to the Board's report for 1925, the number of local authorities who had provided any accommodation for defectives was only 17 out of the 124 under the Act. Very slow progress continued to be made, and this was quite inadequate to the urgent needs of the situation.

Meanwhile, matters were further complicated by the ever-increasing number of post-encephalitic patients whose immorality and criminal conduct, the outcome of this disease, constituted a serious problem. Their case was not met by the Mental Deficiency Act of 1913, according to which mental defect must have existed from birth or from early years. To meet the need of placing such sufferers in appropriate institutions where they would receive the necessary medical treatment, the Mental Deficiency Act of 1927 was placed upon the statute-book. This Act, by altering the definition of the four categories of mental defectives given by the Act of 1913, enabled provision to be made for post-encephalitic and other cases "of arrested or incomplete development of mind existing before the age of 18 years, whether arising from inherent causes or induced by disease or injury." In addition, various difficulties which had arisen as a result of the drafting of the Act of 1913 were removed.

The position, however, with regard to the insufficiency of accommodation is more serious than ever. The Board of Control can be warmly congratulated on the unabated zeal it has shown in urging, day in and day out, the local authorities to fulfil their duties, matters could not have been more plainly stated. Again and again the Board has pointed out the degradation, pauperism, crime, and disease which follow the neglect of the mentally defective, and instance after instance has been quoted.

The present report (for the year 1927) quotes numerous histories supplied to the Board by local authorities, the following instances may be cited.

Father Welsh collier Mother Feeble-minded (1) Daughter born 1895 feeble-minded in institution for three and a quarter years died therein of influenza and pneumonia (2) Son born 1899 feeble-minded in certified institution for four years died therein of bronchial pneumonia (3) Son born 1897, imbecile under care in institution for mental defectives since August 1915 (4) Son born December 1900 imbecile under care in institution for mental defectives since March, 1918 (5) Son born August, 1904 imbecile under care in institution for mental defectives since September 1920 (6) Daughter born October 1908, feeble-minded under care in institution for mental defectives since March 1928. These are the six mentally defective children of one family there were no other offspring.

Father in and out of mental hospital Mother feeble-minded (1) Daughter aged 29 feeble-minded under care in mental deficiency institution since August 1921 (two illegitimate children) (2) Daughter aged 24 feeble-minded under care in mental deficiency institution since March 1921 previously sent to industrial school for consorting with prostitutes (3) Daughter aged 17 imbecile under care in mental deficiency institution since January 1928 found wandering round army camps (4) and (5) Two sons unemployable.

Father described as being fairly normal Mother mentally defective (1) Son aged 14 an imbecile under care in mental deficiency institution since April 1927 (2) Daughter aged 11 feeble-minded under care in mental deficiency institution since April 1927 (3) Son aged 14 feeble-minded in Poor Law institution awaiting removal to institution for mental defectives (4) Son aged 7, feeble-minded under care in mental deficiency institution since July, 1927. The parents of these four mentally defective children have themselves received indoor relief for a number of years.

Such histories afford a glimpse into the devastating effects of neglect to segregate the mentally defective population in our midst. It is even possible, as matters now stand, for mental defectives who have been certified as unable to manage themselves and their affairs, or as requiring care, supervision, and control, to become married. In days of enlightenment these things should not be, and it is the bounden duty of all who have cognisance of the facts to support every demand for the full operation of these Acts.

Scotland.

Extension of the Scottish H use

WE publish in the *Supplement* this week a full account of the ceremony on October 4th, when the extended premises of the Scottish House of the British Medical Association in Drumsheugh Gardens, Edinburgh, were formally opened by Sir Robert Philip, immediate Past-President of the Association.

New Edinburgh Professor

Professor W. T. Ritchie, who occupies the chair of medicine in the University of Edinburgh in succession to Professor G. Lovell Gulland, delivered his inaugural lecture in the anatomy classroom of the University on October 4th. Principal Sir J. Alfred Ewing, who presided, said that the subject of medicine was enormously progressive at the present time, it was becoming increasingly experimental, and, one might say, full of the spirit of adventure. Doubtless the new professor would require more experimental facilities than in the past, although it might be difficult for the University to provide these. Professor Ritchie remarked that there was a striking difference between medicine to-day and that of thirty years ago, corresponding to the changes which had emerged in other spheres of material and intellectual life. The advance in medicine had not been achieved by clinical observation only, but by the application to medicine of knowledge from all branches of science. The fame of a medical school depended to a considerable extent upon the contributions which it made to the advancement of medical science as well as upon the educational value of its instruction. In Scotland the organization of medical education was, like the forms of Church government and legal procedure, an expression of the history and social life of the country. In the nineteenth century a professor of medicine delivered a lengthy course of systematic lectures, supplemented by clinical instruction, and his departmental needs were met by some simple laboratory apparatus. In the twentieth century, however, a professor of medicine needed not only clinical material, but a department in which the staff could investigate some of the dark places of internal medicine and the student could be brought into close touch with the subjects he was studying. To illustrate his teaching the physician needed the patient, and it might be wondered why some or all of the instruction in the course in Practice of Medicine was not given within the Royal Infirmary. Problems such as this could be solved by a spirit of sympathetic co-operation between the various components of the medical school. The speaker concluded by saying that if generous benefactors were to reconstruct, equip, and staff the department of medicine, and to endow research fellowships in medicine, they would be conferring inestimable benefit not only on the University of Edinburgh, but upon medical science generally.

Scottish Association of Insurance Committeees

The sixteenth annual conference of the Scottish Association of Insurance Committeees was held at Elgin on September 21st and 22nd. Mr H. W. Graham, who took the chair, remarked that passing events had conspired to delay the development of health service which was ultimately inevitable, under the domain of national insurance medical benefit was still confined to irreducible minimum services, but this would before long be much expanded. The announcement that the present pharmaceutical service would be continued led to a lively discussion. Dr E. K. Mackenzie criticized the official means employed to bring about a reduction in the cost of prescribing, and contended that the method of surcharging medical men was making insured persons the scapegoats of the Act. He believed that medical men throughout the country, in order to escape being surcharged, were differentiating between their insured and non-insured patients. He also objected to the attempt which was being made to prevent medical men from prescribing flavouring agents. Sir Henry Keith, in objecting to this amendment, said that it was the wish of the Executive to get the best medicine and the best attention available for the insured person but it was necessary if supervision should be exercised over the cost.

No charge was made against the medical profession as a whole, but amongst insurance practitioners some required to be watched in regard both to the character of the drugs they prescribed and the frequency with which these were given. He believed that some young doctors should have a careful education in prescribing in a druggist's shop, so that they might know the real value and the effect of quantities. The amendment to the report was finally defeated by a large majority. An address delivered by Dr Hugh Miller contained a plea for the lessening of what he termed "the prestige of the bottle." He said that often the only thing that a patient desired, and sometimes the only thing that a doctor could do for him, was the prescription of a bottle. There was undoubtedly a movement to lessen the prestige of the bottle, but so long as most consultants continued to prescribe as freely as they generally did it was difficult to persuade insured persons that drugs were not essential in all cases. The speaker believed that there was room for institutions—run on more modest and economical lines than the general hospital—where cases of ordinary illness could be adequately treated and nursed, he thought that with such institutions it would be possible to check illness at an early stage, and that they would, further, have an educative effect on the people. He believed that it was being realized more and more that the worker's home was not an ideal place in which to treat illness, and that sooner or later the problem of providing suitable accommodation would arise. Dr J. Parlane Kinloch, medical officer of health for Aberdeen, delivered an address on the adequacy of the medical service, in which he said that the present inadequacy of the hospital system was likely to be remedied by the unification of the health services proposed in the Government memorandum. There had, so far, been a failure to link up the general medical practitioner with the official public health service of his area. No medical service, however, would ever be adequate unless the general medical practitioner was an integral part of it, and at the present moment the British Medical Association was giving earnest consideration to the question of enabling the general practitioner to take his part in the health service scheme. Public medicine had to some extent encroached on private practice with the sanction of the legislature, but the speaker believed that public health organization would fail to provide an adequate medical service for the community until the general medical practitioner became an executive medical officer within the service. They might assume that the school medical service and the purely domestic service were to be transferred to the town councils under the present Government proposals, and it was almost inevitable that with such a transference there would be an extension of these two services. He thought that the time had come when the general medical practitioner should be re-established in his position of full responsibility as family doctor—responsible for watching over the family health, and for the prevention of disease with the help of the whole official machinery that the local authority had provided.

Sanitary Congress at Ayr

The fifty-fourth annual congress of the Royal Sanitary Association of Scotland was held at Ayr from September 5th to 8th, when over three hundred delegates were present from county councils and other local authorities throughout Scotland, and from various cities in England. Dr A. S. M. Macgregor, medical officer of health for Glasgow, presided. Colonel P. S. Lelcan, professor of public health in the University of Edinburgh, read a paper on public education in the art of health. Referring to the cost of sickness, he said that in Scotland during the year 1927 the destitute sick had cost the community £360,000, the mentally unfit £910,000, the maintenance of hospitals £2,185,000, while under the national health insurance scheme medical benefit had cost £951,000, and sickness benefit £2,124,000. It might be estimated, further, that about £3,000,000 was spent in connexion with sickness by the uninsured persons in the community. In addition to these disbursements, however, the nation also lost the value of the work that the sick would do if they were fit. Seeing that the 1,800,000 insured persons lost on an average fifteen and half days' work each year on account of sickness lasting

more than three days, it was a fair assumption that there was a yearly loss to the State of 7,400,000 weeks' work, which might be valued at £22,110,000. The total annual loss for Scotland produced by sickness might therefore be put down at the arresting figure of £31,461,000, while behind this loomed a sinister mass of uncalculable items which was probably larger still. This want of fitness had been indicated by the wartime discovery that in some districts 80 per cent of the mulo population were unfit for front line service. There was a marked contrast between the losses due to strikes or unemployment, and the heavier losses caused by sickness. The crushing burden of rates upon industry was increased by the cost of treatment and benefit of sick workers hanging on to those remaining fit, who were already staggering under the load, in Scotland every six workers, including women, had to support on an average eleven other persons, including one breadwinner who was sick. Turning to the causes of unfitness, the speaker said that even at the end of last century it had been computed that the universal application of the knowledge which then existed in regard to communicable diseases would permit of their eradication within fifty years. The knowledge of the general public, however, lagged hopelessly behind, for they had never yet been systematically taught even the elementary principles in the art of healthy living. The boards which had examined 2,400,000 men for war service concluded that out of every nine men of military age three were fit, two were decidedly infirm, three could almost be described as physical wrecks, and the remaining man was a chronic invalid with a precarious hold on life. The latest recruiting figures still showed that Scottish recruits were being rejected as unfit at the rate of 34 per cent. Unwise choice of food and bad cooking were responsible for a great deal of illness, so that digestive troubles ranked second in the list of ailments causing lost time, of which they accounted for one-fifth of the total. It had been shown also that cool fresh air was a great preventive of disease. From a host of examples might be taken the fact that raising the heat in schools by 70 F had reduced the work done by 10 per cent, and raised the sick rate by 18 per cent, and the respiratory diseases rate by 70 per cent. Similarly in cotton factories the same rise of temperature had reduced the workers' output by 15 per cent, and a rise of 15 per cent had caused a 25 per cent drop in work by the spinners. Other matters affecting health were debated at the congress. These included a discussion on the subject of simplifying the nomenclature of the grades of milk, and the congress resolved to communicate with the Board of Health and the Board of Agriculture with a view to having a revision carried out. Judge Andrew M. Hunter, convener of the public health committee, Avr, read a paper on the need for simplification in certain aspects of public health administration. This dealt largely with a consideration of the recently issued White Paper, in which it is proposed to hand over to county and other authorities the services in the smaller burghs affecting housing, town planning, hospitals, infectious diseases, maternity and child welfare, sale of food and drugs, water, drainage, and prevention of river pollution. A discussion on housing was introduced by Mr W. F. Hamilton, who considered that the problems involved were more difficult in the smaller burghs than in the large centres. The future of municipal services in regard to the treatment of tuberculosis was also discussed. Dr John A. Wilson, assistant medical officer of health for Glasgow, expressed the opinion that there was need for further development of the outdoor clinic in connexion with non-pulmonary tuberculosis, the hospital treatment of pulmonary tuberculosis had served a valuable function in removing highly infectious cases from overcrowded areas, and so limiting the spread of infection, even if it had not produced any appreciable alteration on the course of the individual case.

Banffshire Nursing Association

The annual meeting of Banffshire County Nursing Association was held on September 18th, in Gordon Castle, Fochabers. Lady Findlay of Aberlour presided, and in reviewing the work of the past year said that the scheme

of county nursing had been working hand-in-hand with public health activities under the medical officer of health and the education authority. She believed that no district which had a nursing association would wish to go back to the former state when a nurse was not available, and she hoped that in a short time every district in the county would be provided with a nurse.

Ireland.

Royal Victoria Hospital, Belfast New Maternity Scheme

Her Excellency the Duchess of Abercorn and Professor Lowry of the Queen's University of Belfast recently visited Londonderry, addressing meetings in connexion with the new maternity scheme, in order to obtain assistance for the building of the maternity wing of the Royal Victoria Hospital at Belfast. At a meeting of women held in the Mayor's Parlour, Londonderry Guildhall, on October 5th, the view was unanimously expressed that those interested should give all practical assistance to the Belfast project, and it was agreed that when the Londonderry scheme was set on foot it would receive their whole-hearted support. The question of providing facilities for ante-natal supervision and treatment in Londonderry and the district was emphasized.

Hospital Finance in the Free State

In a recent special article in the *Irish Times* on the finances of Irish voluntary hospitals the balance sheets of five hospitals, representing a total of about 600 beds, have been analysed for the two quinquennial periods 1909-13 and 1922-26. It is not claimed that the analysis is complete, this, indeed, would be impossible owing to the want of uniformity in the preparation of hospital balance sheets, but certain striking points are brought out. The total expenditure of the five hospitals for the first of these periods was just over £192,000, and for the second period £367,000—an increase of £175,000. Stated otherwise, an annual sum of £38,000 was required for the maintenance of these 600 beds in the pre-war period, as compared with £73,000 in the post-war period. No details concerning expenditure need be given, but in answer to possible criticism it may be stated that a portion of the sums named in each period was employed in new construction and in additions to existing buildings. With the advance of medical science, however, modifications of existing structures are repeatedly required, any sum thus spent may be regarded as ordinary expenditure. It may be asked whether there is any evidence of a decline in expenditure since 1922. A comparison of the actual expenditure for the year 1922 with that of 1926 shows that there is not, in the first of these years the expenditure was, in fact, a few hundred pounds less than in 1926. In considering income it is important to consider how the additional expenditure in the post-war period has been met. Only three important sources will be considered—pay-patients, subscriptions, and dividends from invested funds—but it may be added that the grants made by the Hospital Sunday Fund, by the corporation of Dublin and by other townships, and the payments made to some hospitals for special services, are much valued by all hospital secretaries, owing to the fact that they can count, with a fair degree of assurance, upon the amounts derived from these sources. The most cursory survey shows that the income derived from pay-patients has been largely the means of preventing the hospitals from passing into bankruptcy. In the period 1909-13 the total income from pay patients amounted to only £10,315, while in the years 1922-26 no less than £120,258 was obtained from this source. This is a fact that the public should fully realize. Hospital abuse has practically disappeared in the old sense of the word, while in its place there is a tendency for a new abuse to arise, through the fact that there is sometimes difficulty in securing the admission of a patient who is unable to pay something for maintenance. This is economically unsound, it is obvious that a sick person,

dependent only on insurance money, may at times be compelled either to leave his family to starve or to refrain from seeking hospital treatment. It should be remembered that it was for this very class that the hospitals were originally founded, and that it is to help them that voluntary subscriptions are forthcoming. Moreover, the establishment of a class of pay-patients in public hospitals has gradually led to a change in the relation of hospital patients to the staff of a hospital. Formerly no member of a hospital staff received any payment from patients treated by him in a public hospital, now in some hospitals it is agreed that members of the staff may take moderate fees from patients paying for their maintenance. Looking ahead it seems likely, indeed, that isolated private nursing homes will tend to disappear, and that in their place private wings will be attached to the public hospitals. This has taken place in many other cities, and makes for both efficiency and economy. It is important to consider whether the hospitals can depend upon a steady or increasing income from pay patients. Unfortunately, an examination of the figures suggests that the maximum has been reached, and, indeed, passed. In 1922 the sum of £27,800 was obtained, as compared with £22,900 in 1926, the difference is probably due to the fact that in the former year several hospitals received into their wards army pensioners, who were paid for by the British Government. No further decline in the present figures seems to be likely, but it is extremely improbable that more than £22,000 annually can be raised in this way. The term "subscriptions" includes special donations and legacies, it is a common belief among hospital governors that the revenue from this source has declined, and, as a matter of fact, there has been a fall in some hospitals, but when the figures of the five hospitals are examined as a group, the rather surprising fact emerges that £76,000 was obtained in 1922-26, as compared with £64,000 in 1909-13. The increase is perhaps due in part to special appeals, but special appeals are among the recognized methods of obtaining hospital funds. Those hospitals that have undertaken special appeals, of course, show the results in their balance sheets, while those who have abstained show a decline in their subscription list. Only a trained auditor could give an accurate account of the income derived from invested funds, as some of these funds are specially earmarked for special purposes. It may, however, be stated at once that, although one among the five hospitals under consideration has apparently been compelled to sell a portion of its securities in order to pay its overdraft, the total income from dividends has increased by about £1,000 per annum. In 1909-13 the average annual income was just under £9,000 in the later period it was just over £10,000. In other words, investments must have increased in the interval by about £20,000. This fact is, of course, highly satisfactory, but at the same time it must be realized that even if this £20,000 were expended immediately for the purpose of wiping out debts, it could only be regarded as a temporary expedient.

Finally, the actual present position regarding the Irish voluntary hospitals may be considered. The combined overdraft of these hospitals at the beginning of the current year amounted to just over £40,000 but on the other hand, the additional debt incurred during 1927 was less than during previous years. It seems likely, in fact, that if the overdraft could be wiped out these hospitals could carry on satisfactorily on their present basis, and would be able, at any rate approximately, to balance their budgets. The accumulated debt, however, is pressing heavily, and requires a considerable sum yearly in interest, and it must be admitted at once that there does not appear to be any immediate prospect of reducing it to any extent. It has been suggested that the number of beds might be diminished, and that too many hospital beds are maintained in Dublin. This last statement can be denied, there are no more beds maintained in Dublin in proportion to the population served, than there are in other large centres, and every hospital has had a waiting list during the greater part of the year. The writer of the article is not prepared to offer any solution of the hospital problem, but he hopes that his presentation of the facts may provoke a more general discussion of the matter and excite more interest than has been shown recently.

England and Wales.

Theory and Experience in Medicine

SIR ARTHUR KEITH addressed the annual meeting of the Chartered Society of Massage and Medical Gymnastics, held in London on October 5th, on the conflict between theory and experience in the practice of medicine. He began by recounting an incident in his early career, forty years ago, when, in the company of an old practitioner, he visited an upland farmhouse in Aberdeen to see a patient who was prostrate with deep-seated pain in the back. The practitioner proceeded, by dry cupping, to dilate the superficial vessels, and brought about complete relief. Here, to the young man's astonishment, science and empiricism were shown in conflict, and empiricism won, hands down. That was typical, said Sir Arthur Keith, of the conflict which had been going on in medicine for centuries. In any medical journal of any period would be found articles in which the competing claims of science and empiricism were canvassed. It was out of such conflict that medicine advanced to higher things. Young men and women entered the profession with high resolves to make science their sole guide in practice, and soon discovered themselves involved in this conflict. The conception which he himself had formed of science at the time he entered medicine was represented by the kind of knowledge which had been revealed by Pasteur or by Koch in their respective spheres. He set out with the idea that science was creative and should always precede practice, and he had gone a long way on his medical journey before he discovered that he had formed an altogether wrong conception of science. Science performed her best service, not by moving ahead of practice, but by following in the rear. Cod-liver oil furnished a homely example, it had been used by medical men for generations, though science found no virtue in it, and then, in modern days, came the discovery of its particular value, to justify the medical faith which had been born of experience. During the long and dry winter in Newfoundland the natives lived on salt pork, margarine, and preserved vegetables, in the spring many of them suffered from night blindness. The popular remedy was bird's liver, raw or cooked. Twenty years ago this would have been thought an example of superstition, but again science had provided the justification. Captain Cook's exacting dietetic rules for his crew, whereby the sailor who refused to eat his ration of vegetable hash suffered stripes on his bare back, were successful at the time and had since been justified by the scientific explanation forthcoming in the twentieth century. Edward Jenner found by experiment that he could confer on human beings immunity from small-pox by inoculating them with cow-pox. Jenner could not explain it in scientific terms, but the method he had employed empirically was employed afterwards scientifically by Pasteur, though science had not even yet ousted experience in treatment by immunization. Quinine, digitalis, opium, arsenic, mercury, and many other useful drugs had been brought into treatment, not as the result of scientific inquiry, but of chance discovery. The value of light as a therapeutic agency of the highest value was not a modern discovery for there never had been a time when human beings did not instinctively bask in the sun. Science played a twofold part in medicine, sometimes moving ahead of practice (as in glandular therapy), and sometimes justifying experience, so that science and experience ultimately became reconciled. It might be said, then, that there was no real conflict, but there was real conflict between magic or superstition on the one hand and science on the other—a conflict in which there could be no compromise or reconciliation. The body was endowed, said Sir Arthur Keith in conclusion, with certain recuperative powers, and all that science could do was to assist them. But these powers came into exercise also after the charlatan had had his innings and for this circumstance, of course, the charlatan took the credit. There were numbers of people in this country as superstitious, in a medical sense, as the natives of Africa who believed in their rain doctors, and when the rain came gave all the credit to the magician, while the thunder cloud received none.

Retirement of Dr F M Tindall

On the occasion of his retirement from active practice Dr Frederick M Tindall of Bedlington, Northumberland, was entertained at a complimentary dinner in the Queen's Head Hotel, Morpeth, on September 26th, by a number of his professional colleagues and other friends, and was presented with a massive silver salver, suitably inscribed. Dr H S Brown presided, and the presentation was made by Mr George Baker, who said that the departure of Dr Tindall from the district where he had laboured for thirty-two years would leave a gap that would be very difficult to fill. In his reply, Dr Tindall recalled the working conditions of the colliery surgeon thirty years ago, and compared them with those now prevailing, adding that all would agree that great progress had been made from both the medical and social standpoints. Tributes to his professional and social qualities and to his position in the field of medicine were made by Drs Beaton, Dickie, Hudson, and others. Dr Tindall, who graduated at the University of Aberdeen in 1886, is a past-chairman of the Blyth Division of the British Medical Association and a justice of the peace, he is now taking up his residence at Bridge of Allan, in Scotland.

A London Child Guidance Clinic

The Jewish Health Organization of Great Britain maintains, at the Jews' Free School, Bell Lane, Spitalfields, E, a child guidance clinic for the study and treatment of maladjusted and delinquent children and adolescents of any race or creed. Advice is given also on special problems, such as the need for vocational guidance and the placing of mentally or otherwise defective children requiring institutional treatment. The clinic is also prepared to undertake the examination of young offenders and young persons whose conduct betrays abnormality, and to supply reports to magistrates and teachers. Children may be sent into the country or temporarily placed with foster parents or in convalescent institutions according to individual requirements, in certain cases special training is prescribed and arranged. School care committees have been co-operating with the clinic by referring cases, by collecting information, and by assisting in the suitable placing of cases. The staff of the clinic consists of two psychiatrists, a psychologist, and a specially trained social service worker, it is open on Mondays, Tuesdays, Wednesdays, and Thursdays from 5.30 p.m. to 7 p.m. Students of social science who intend qualifying for mental welfare work are afforded opportunities for practical training, while the material accumulating in the course of the work is at the disposal of research students at all times. It may be recalled that, as recorded in our issue of June 2nd (p. 957), the Education Committee of the London County Council recommended the acceptance of an offer by the Child Guidance Council for the establishment of a child guidance clinic similar in scope and aims to that described above, and that this clinic is to be established next year.

Correspondence.

BAYLISS AND STARLING MEMORIAL

SIR,—May I take advantage of your correspondence columns to draw the attention of your readers to the fund which is being raised to provide a memorial to the late Professors Sir William M Bayliss and E H Starling?

Many subscriptions to this fund have now been received from all parts of the world, and the committee is particularly grateful to those contributors in foreign countries who have so liberally assisted. Although a considerable sum has now been raised, this is not quite large enough to provide a good annual studentship.

In thanking those of your readers who have so generously assisted the fund, may I remind those who intend to do so but have overlooked the matter that subscriptions may be sent to me at the Department of Physiology and Biochemistry, University College, Gower Street, WC1, and cheques should be crossed "Bayliss Starling Memorial Fund"—I am, etc.,

London, W C Oct 5th.

O LOYATT EVANS,
Secretary of Committee.

RADIUM IN THE TREATMENT OF CARCINOMA CERVICIS

SIR,—It is questionable to what extent a controversial correspondence advances any given problem. So often it degenerates into personalities and causes bitterness.

My excuse in the present instance is the fact that the paper by Mr E Farquhar Murray in your issue of October 6th (p. 609) is liable to do a great deal of harm to the progress of the treatment of carcinoma of the cervix uteri, and I am sure that the author will accept my remarks in the spirit in which they are written.

The fact that from his paper it is obvious that he is not biased against radium makes it all the more regrettable that he has obviously not had time to read any of the recent literature, and is using a technique that was given up by the rest of the world at least five years ago.

Many of the points he raises, such as the advisability of using radium before performing Wertheim's hysterectomy, are far from settled. Surely, however, he does not base his conviction that radium has not "superseded the radical operation" on the eighteen operable cases that he has treated with a hopelessly inadequate dose? The technique of radium treatment of carcinoma of the cervix uteri is still a long way from being standardized, but there are at least two recognized methods by which the local growth can be made to disappear in practically 100 per cent of operable cases.

The problem before us now is how to deal with those cases where the glands are involved. This is being tackled at St Bartholomew's Hospital, both by x rays and intra-abdominal insertion of radium. Whatever the future technique may be, there is one thing quite certain, that we shall never go back to putting 50 milligrams of radium element up against the cervix for twenty-four hours—I am, etc.,

MALCOLM DONALDSON

London W 1, Oct 6th

PULMONARY ASBESTOSIS

SIR,—Dr Cooke (September 29th, p. 585) offers objection to certain opinions which I ventured to express with regard to the curious brown bodies found by himself and others in cases of pulmonary asbestosis. As to their diagnostic value in this disease I merely stated that, so far as I was aware, they do not occur except in the lungs of asbestos workers. It is most unlikely that such striking and remarkable bodies have been missed by morbid histologists in the past, and I submit that if Dr Cooke would demonstrate their presence in the lungs of other than asbestos workers it would be much more convincing than theoretical deductions from *in vitro* experiments. They have not been present in any lungs, silicotic or otherwise, which I have examined microscopically, save only the four cases of asbestosis which we have encountered in Leeds. Six other fatal cases of this disease have been reported so far, and in all of them the bodies were present in abundance. Simson, in South Africa, investigated as controls sections of lungs from a large number of Rand miners who had died from silicosis and tuberculosis. The results were in every case negative.

The opinion which I expressed (not an original one) that these bodies are derived from the inhaled asbestos dust follows naturally from what has been said. I admit that complete proof is lacking, but I do not agree that Dr Cooke's observations "suggest diametrically opposite conclusions." Rotation of the plane of polarized light and a particular x-ray pattern are related to the structure of the asbestos, and these properties are not necessarily retained when this substance has had the opportunity of undergoing changes, physical or chemical, as a result of prolonged immersion in the body fluids. The fact that the peculiar bodies have a lower content of iron than certain samples of asbestos dust is also no argument against the hypothesis, since there may have been an addition of iron-free substances to the original material. Various physico-chemical possibilities in these and other directions are discussed by both Stuart McDonald and Simson.

I look forward with keen interest to the results of Dr Cooke's experiments on the silicating of micro-organisms, but would warn him that I shall take some convincing that the peculiar bodies of asbestosis are in any sense organismal in nature.—I am, etc.,

Leeds Oct. 4th.

M J STEWART

CLINICS FOR ACTINOTHERAPY

SIR,—The medical profession has been circualized by a company styled National Sun Ray and Health Centres, Ltd., which proposes to open clinics for the administration of retinotherapy and physiotherapy in London and the provinces. I leave space to comment on some of the statements therein, and in particular on the plea made for the support of the profession.

Among the chief reasons given for the formation of the company are an increasing public demand for ultra-violet light treatment, and the inability of the busy general practitioner to afford the time to supply this demand individually, or to study a specialized and comprehensive branch of therapy. Surely, Sir, it is common knowledge in the profession that wherever there is a supply of electricity there is now a doctor, whether he be general practitioner or specialist, who is conversant with the recent literature on this subject and prepared to give ultra-violet ray treatment to suitable cases individually, in privacy and comfort.

Let us examine another statement.

There is a regrettable tendency for these valuable therapeutic modes to become discredited owing to their misuse by the unskilled and unqualified. It is hoped that the medical profession will realize that this company's activities will offer it an excellent opportunity for retaining such modes of therapy under its own control whilst avoiding the necessity for actually providing such treatment itself.

This company is not a charitable concern designed to relieve or assist in the work of the great voluntary hospitals. We may assume that its shareholders hope to obtain a reasonable return for their investments. They will no doubt take steps to "tell the world" what wonderful boons they are prepared to bestow upon mankind. Presumably the blessing of the profession is solicited as an important part of the advertising scheme. And we to see in glaring type in the lay press "Under medical supervision," "Supported by the British Medical Association," "Supported by the medical profession," above a long list of the diseases which the company has treated with conspicuous success?

Thousands of medical men and members of the Chartered Society of Massage and Medical Gymnastics (who are pledged to work only under medical supervision) are expert in the administration of physio-therapeutic measures and have sunk capital in expensive plant. There is no member of the community who is now debared from the advantages of such treatment by reason of expense or lack of facilities.

Is a company with a big financial backing and employing medical men to be allowed to advertise when the humble practitioner does so at the peril of his career? What, too, will be the position of the "whole-time registered medical practitioner experienced in this branch of medicine" who is to be in charge of each centre? As a unit in a business concern he must endeavour to make things pay, and his efficiency, one imagines, will be judged by business men according to the profits which he shows in his returns. He must be prepared to treat patients who come to him as the direct result of advertisements in the lay press on their own initiative and without the knowledge of their own doctors. He will lose, therefore, the advantage of any previous knowledge of the patient's condition and idiosyncrasies, and it is doubtful whether he will have the time to investigate these thoroughly on the spot. Day by day he will be subject to the insidious temptation to take the run that every applicant is a suitable, or at all events a not unsuitable, case.

I should have thought, Sir, that any medical man of standing would decline to take service in a treatment concern which does not give him a free hand and does not keep its activities within the recognized limits of medical etiquette and ethics.

The profession is being asked to give its support to a company which, to suit its policy and financial returns, may decide to undertake any form of treatment, whether by physiotherapy, drugs, appliances, or manipulation. To some it may seem a trivial matter to lend name and influence to a scheme to exploit ultra-violet ray treatment, but what is there to prevent an extension to surgery, diseases of the ear, nose, throat, eye, and skin?

What is there to prevent a company being floated to provide orthopaedic or skin treatment and living as one of its "reasons d'être" that "the activities of unqualified persons who exploit these methods for gain, at the expense of the public, will best be combated, and they look forward with confidence to the co-operation of the medical profession." Bone-setters and beauty specialists may and do exploit the public, but the orthopaedic surgeons and dermatologists do not require the assistance of a company formed for profit in putting their house in order.

The circular letter may be characterized as an attempt to gain the blessing and support of the profession for a scheme the lines of which cut clean across the principles which the profession has always upheld as being in the best interests of the public.

The profession looks to the British Medical Association to lead it in these matters. I trust that the Ethical Committee, and through it the Council, will lay it down in no uncertain terms that if any trading company, one of whose objects is the cure or treatment of disease, wishes to have the support of the Association and profession it must conform to the rules which govern the private practitioner—I am, etc.,

Newcastle upon Tyne Sept 27th

WHATELY DAVIDSON

ANAESTHESIA FOR TONSILLECTOMY AND
REMOVAL OF ADENOIDS

SIR,—I am much interested to see from the letter of Dr. A. H. Morley (September 29th, p. 585) that attention is being drawn to the safety and efficiency of the anaesthesia for tonsil and adenoid operations. I cannot agree with all his points, for, in my opinion, nitrous oxide gas and oxygen is the ideal anaesthetic for the safety and comfort of the patient, and with an efficient machine gives the operator as much time as he wants for the operation. In fact, it is the usual anaesthetic in the United States of America, and to a large extent in Canada also. I can many tonsil and adenoid cases operated on, the method generally was to separate off the anterior pillar of the fauces from the tonsil, sometimes by blunt dissection and sometimes with a knife, then to remove the tonsil by means of a snare, bleeding points were ligatured with catgut, sometimes as many as a dozen points were tied, and all oozing stopped. The average time was ten to fifteen minutes, against the usual two minutes of the English surgeons who use a guillotine. Mostly the operations were done sitting up in a dental chair. I never saw any trouble with the anaesthetic. I agree that if you are going to use ether any way a Clover's inhaler is the best method, and certainly does prevent shock to a large extent. The article by Sir Charters J. Symonds on the method of employment of Clover's inhaler (September 29th, p. 581) is instructive. When I was taught it we always used nitrous oxide for induction and then followed on with ether.

There is an article in *Anaesthesia and Analgesia* for August, 1926, entitled "A report on the use of carbon dioxide 25 per cent and oxygen 75 per cent and its effect on the reduction of the coagulation time of the blood," by Cline N. Chipman, M.D., anaesthetist, Washington, D.C. He says:

About one year ago Dr. Ben Morgan informed me that carbon dioxide 25 per cent and oxygen 75 per cent when used in a closed inhaler would produce general anaesthesia. Knowing the work Professor Landell Henderson, Dr. W. H. Haggard and others were doing with carbon dioxide to stimulate respiration I was anxious to use the higher percentage of CO₂ with oxygen and see the results. I started using CO₂ 25 per cent + oxygen 75 per cent in adult tonsil cases as the preliminary anaesthetic in place of nitrous oxide-oxygen. The CO₂ 25 per cent + oxygen 75 per cent was started and it was found that after six to ten inhalations the patient was unconscious. Then ether was admitted to the mixing chamber until the patient was anaesthetized. He was then transferred to the operating table where the anaesthetic was continued by the vapour method. It was marked from the first that the patient was anaesthetized quicker and without any resistance or struggling.

He goes on to say that there is reduced bleeding and quotes many tables to show that the coagulation time of the blood is reduced by CO₂ 25 per cent and oxygen 75 per cent followed by ether. The article is much too long to quote fully. I have quoted so much to show that carbon dioxide can be used direct instead of waiting for the

percentage necessary to be built up from the patient's own respirations

I have used the method myself several times, and can vouch for the speed with which patients can be thoroughly anaesthetized with it—I am, etc.,

Dorcas er Oct 4th

E J CHAMBERS

TRAUMATIC ASPHYXIA

SIR,—Lieut-Colonel Coullie's interesting note upon traumatic asphyxia (*Journal*, September 28th, p 569) prompts me to record a similar case seen in September, 1923. I was called to the patient at hospital late one night as a possible case of head injury, and the following notes were made the next day.

Mr — aged 50. He has enjoyed good health until seven years ago. He then began to have curious attacks, which he describes as follows. He would quite suddenly find himself looking upon a panorama which he at once recognized as being that of Cerbere, a small town in the Pyrenees, which he has never visited, but which he knows well by name in that he has had business dealings with the place. This vision is quite transitory but leaves him feeling a little dazed so that at times it has interrupted his conversation. He will also at times wake in the morning feeling that he has dreamed the same vision. On these occasions his wife has often remarked that he has breathed heavily and kicked during the night. On one occasion he found on waking from one of these dreams that he had bitten his tongue and passed water in the bed. There is thus no doubt whatever that he has been suffering from minor epilepsy.

To-day at about 2 p.m. he was driving his car from his office along the Tower Bridge Road with his son sitting next to him. His son noticed the car suddenly slowing down and turning to his father found him apparently bending forward over the wheel. He at first thought he was trying to make an adjustment to the gear lever. Finding however that he did not reply to a question the boy took out the gear and put on the brake. He then found his father unconscious and intensely cyanotic.

The patient was forthwith brought up and admitted to Guy's. On admission he was quite conscious and no abnormality was detected in his reflexes. His left eye was bloodshot with a subconjunctival haemorrhage in the outer canthus. This eye was also slightly protruded. His pulse on admission was 84 subsequently it fell gradually to 60. When I saw him at 1 a.m. both eyes were definitely protruded and the outer canthus on the right, and the whole conjunctiva on the left suffused with scarlet blood. There were small petechial haemorrhages all over the scalp and the upper part of the cheeks and also on the posterior part of the soft palate. There was also a well marked ring of petechial haemorrhages around the neck more on the right side than the left at the point where one might suppose his collar to have been. On inquiry it appears that he has always been in the habit of wearing a very tight collar and this was not released for some minutes after the fit probably not for a quarter of an hour.

The patient is perfectly clear and sensible and gives an excellent account of himself. The fundi are normal there is no paralysis of the cranial nerves. The right side of the face seems to move rather less than the left especially in expressional movement. The tongue is protruded slightly to the right. The wound of a recent bite is present on its left margin. No other abnormality in the nervous system or elsewhere was detected. Heart normal. Spleen not palpable. Temperature normal.

The proptosis in this case was very striking and had suggested a fractured base to those who had seen him.

In view of the long history of epileptic attacks with visual hallucination, I considered the possibility of haemorrhage into a tumour, but thought it probable that the subcutaneous, submucous, and subconjunctival haemorrhages were due to the intense congestion of the epileptic attack aggravated by the tight collar.

Two days later the proptosis of the right eye was almost gone and that of the left eye much less marked, and I concluded that the second alternative was probably correct—I am, etc.,

London W. L.

C P SYMONDS, M.D.

SECURITY OF TENURE IN PUBLIC POSTS

SIR—I notice in the correspondence columns of your issue for September 28th (p 587) a letter from Dr H C McManus, in which he gives to those thinking of entering the public services a warning on the important subject of security of tenure of medical appointments under such local authorities as boards of guardians, county boroughs and county councils. Speaking as one who has held public appointments in a full-time capacity for a considerable number of years, I can assure those to whom Dr McManus directs his words of warning that in practice the danger of dismissal at three months' or any other notice is extremely small, and need not be regarded as a factor of

any importance in the consideration of whether to enter the public services or not.

In theory it is, of course, quite correct to state that a public body has in general the legal right to dismiss a medical officer without assigning a reason for this action and without any sort of impartial inquiry. Even this statement is only partially correct, as many medical officers of health cannot, by the terms of their appointment under the Sanitary Officers' Order, be dismissed without the consent of the Ministry of Health. This consent is given after a most careful inquiry, at which the medical officer concerned is afforded full opportunity to present his case, and only if the grounds for dismissal are entirely adequate. Appointments of this kind are, however, only a small proportion of the total number of public health and other posts occupied by medical practitioners, so that, in theory, it is quite correct to say that a local authority has the power of dismissal in the majority of cases, provided that due notice is given according to the terms of the appointment. It is, however, one thing to have this power and, in practice, quite another to exercise it in an arbitrary fashion. Experience shows conclusively that local authorities are, on the whole, extraordinarily reluctant to dismiss any permanent official except upon the strongest grounds, and this reluctance is still more marked when the official has many years of service to his credit. I have never come across a case, or even heard of one, where a doctor has arbitrarily been given three months' notice to leave, just before he becomes eligible for his pension, and I feel sure that many men will serve all their lives under a local authority without an example of this kind coming within their official experience. I am not suggesting that this kind of thing has never happened in the past or will not happen in the future. No doubt Dr McManus, before writing, has had such a case brought to his notice. But the risk of an efficient medical officer being dismissed on inadequate grounds is, in the public services, extraordinarily small, and need hardly weigh in the balance to any extent at all in the minds of those younger medical practitioners who are considering the question of devoting their professional career to the public services. Most of us, indeed, regard the security of tenure in a public appointment as, to all intents and purposes, absolute, granted a not too exacting minimum standard of efficiency and reasonable conduct, and this is admittedly one of the attractions of official employment to the minds of many people.

On the whole, except perhaps in the matter of salaries, local authorities treat their officials, and especially their senior and professional officials, extremely well, and instances of really serious injustice on the part of a council or committee towards a member of their staff are few.

It is an imperfect world, and medical practitioners in the public services have to put up with many things, but fear of dismissal is not one of these. To speak candidly, local authorities generally err in the opposite direction to that suggested by Dr McManus—I am, etc.,

W M FRAZER,

Medical Officer of Health, County Borough of Dewsbury

October 2nd.

SIR,—Dr McManus has rendered a public service by his letter on security of tenure in public posts. These facts should be well known and not concealed as at present. In 1921 I was glad to read that the British Medical Association had succeeded in getting security of tenure for medical officers of health. I have ever since been trying to ascertain whether this did or did not also apply to assistant medical officers. Since it as yet does not, it is to be hoped the British Medical Association will again exert its influence to obtain this measure of justice for this large body of doctors. Obviously a pensions scheme is a mere farce unless there is security of tenure.

I see in the October number of the *Fortnightly Review* an article headed 'The growing burden of the rates,' in which it is stated that all employees of local government authorities have security of tenure. The sole exception apparently is the body of assistant medical officers. This amply explains the rather low status of these doctors.

Since the Local Government and Other Officers Superannuation Act, 1922, came into force the only effect it has

had has been to render local authorities unwilling to appoint any but the youngest available candidates. Older and more experienced doctors are passed over in favour of younger candidates. Skill and experience are less desirable than youth. The local authorities are thus showing themselves plainly unwilling to pay pensions to the doctors, and it is conceivable that in the years to come Dr McManus's "extreme case" is only too likely to happen.

Let us hope that the doctors concerned may become articulate, nay, vociferous, and that the British Medical Association will champion their cause effectively.—I am, etc.,

October 1st

BACTERIAL FLORA OF THE INTESTINE

SIR,—I observe that Professor Cruickshank, in his address at Cardiff (September 29th, p. 555), has seen fit to admonish "certain bacteriologists" for various heresies. I gather that he has honoured my paper on residual vaccines as representative of the outpourings of this class of person. I therefore find myself singled out as their representative.

Professor Cruickshank demonstrates that the intestinal flora vary greatly in health and he believes that the mere presence of an abnormal organism in the faeces would suggest to "certain bacteriologists" the desirability of a vaccine. He believes wrongly. He then cites a number of organisms named by me as probable causes in various intestinal toxæmias occurring in some individuals. Among other organisms quoted was *B. coli communis*. This last organism was so classed because, although presenting certain abnormalities it appeared to resemble the colon bacillus rather than any other organism. But a vaccine was not made unless the organism formed a high proportion of the total flora. Such a position would have been obvious if the statement in the preceding paragraph had been grasped—namely, that two thirds of the specimens sent for examination were rejected as unsuitable for the preparation of a vaccine.

The incidence of streptococci in rheumatic affections also earns his scorn on the same grounds. I can therefore add together the figures of both groups. 26 cases treated, 75 successful. Professor Cruickshank further states that the results of vaccine treatment cannot be construed as proof of a causal organism. If he is waiting for Koch's postulates to be fulfilled I would refer him to a correspondence on the difficulties of modern bacteriological research which appeared, if I recollect aright, in this *Journal* some months ago.

Any discussion of the actual therapeutic results obtained by me is carefully avoided. They are difficult to explain away and most inconvenient to Professor Cruickshank's own contentions. The chance of these cases resolving spontaneously was assuredly not better than 1 in 10, if, therefore, the association of vaccine therapy with the disease corresponds with the raising of the proportion of successful results to 3 in 4, and that happens over a series of 26 cases, it is a fair assumption that there is a connexion between the two events.

The effect of a high carbohydrate diet and of purging is not such original information as he appears to suppose. I would suggest also that while "certain bacteriologists" are acquainting themselves with the better bacteriology Professor Cruickshank might enlarge his knowledge of the laws of probability and apply it to the figures that I have given. He would then discover that while there is a chance that he is right it is about a hundred times more probable that he is wrong. He also assumes, without a shred of proof, that the intestinal mucosa is invariably intact and capable of resisting the invasion of these organisms and their toxins, and will always remain so. I am ignorant concerning the reference to examining a film of faeces for streptococci.

I have to complain of the evasion of the issues raised in my paper and so must request Professor Cruickshank to apply himself to the following:

1. A case of rheumatoid arthritis on a normal diet and without purging shows on repeated examination a pure culture of some streptococcus in the faeces.

2. What positive proof is there that the patient's intestinal mucosa is impermeable to streptococci and their toxins?

3. An autogenous vaccine is prepared and administered.

4. The patient improves greatly.

5. If the vaccine is not responsible am I to assume that three out of four cases of rheumatoid arthritis will resolve spontaneously? If not why does that proportion improve on an autogenous vaccine?

6. Since I do not believe that the intestine is the only source of bacterial invasion, am I to understand that bacteria in some higher area of the tract, say tonsil and pharynx, cannot cause rheumatism?

I do not claim that my results in vaccine therapy prove with certainty that these organisms can be causal, but I do assert that the results raise that matter from a vague possibility to an arguable probability. Finally, I realize that the fact that all my results were assessed by independent practitioners must have a cramping effect upon destructive criticism. I anticipated Professor Cruickshank.—I am, etc.,

Manchester Sept 30th

C E JENKINS

X-RAY DIAGNOSIS

SIR,—Please accept my congratulations on the inspired common sense of your leading article on "X-ray diagnosis" in the current number of the *Journal*. It should dispel some mental fog on the subject.—I am, etc.,

London W Oct 6th

J H DOUGLAS WEBSTER

SIR,—Surely the difficulties of accurate diagnosis of the case of nictal stone described by Mr C Thurstan Holland and Dr Herbert Williams in your issue of October 6th (p. 601) have been exaggerated.

Pyelography and urography will give all the information that is needed in determining, first, whether a stone is present in the upper urinary tract, and secondly, if a stone is present, whether the kidney is "extensively disorganized."

It is perhaps unnecessary to emphasize the importance to the surgeon, and to the patient too, of the former being in possession of more than one catheter, urethral or ureteric, when he makes an examination of a genito-urinary case.—I am, etc.,

London W Oct 8th.

A CLIFFORD MORSON, F.R.C.S.

The Services

DEATHS IN THE SERVICES

Colonel Llewellyn Thomas Manly Nash, C.M.G., A.M.S. (ret.), died after a long illness in Queen Alexandra Military Hospital, Millbank, on September 9th. He was born in London on April 7th 1861, was educated in the school of the Royal College of Surgeons, Ireland, and took the L.R.C.S.I. and L.K.Q.C.P. in 1884. After acting as medical and surgical resident at the Royal City of Dublin Hospital, he entered the R.A.M.C. as surgeon on August 1st, 1885, was promoted to colonel in the great war promotion list of March 1st 1915, and retired on April 7th, 1918. He served on the north-west frontier of India in the Mianwai campaign of 1891, when he was mentioned in dispatches in the *London Gazette* of September 15th, 1891, and gained the frontier medal with a clasp, and in the Hazari campaign of the same year, receiving a clasp. During the great war of 1914-18 he went to France in August, 1914, with the original expeditionary force, when he was in command of a hospital at Rouen subsequently becoming A.D.M.S. to the 8th Division. In 1915 he was invalided to England and, after serving at the headquarters of the Eastern Command in December 1916 was sent to Blackpool to organize the R.A.M.C. centre there which rose to nearly 20,000 officers and men. In August, 1917, he was appointed A.D.M.S. in Sussex. He was mentioned in dispatches in the *London Gazette* of February 17th 1915, and received the C.M.G. on February 18th 1915. In 1901 he married Editha Gertrude, daughter of the Rev Charles Sloggett.

Lieut. Colonel William Lemon Lane, R.A.M.C. (ret.), died at Southsea on September 1st, aged 78. He was born in India on May 28th, 1850, was educated at Edinbrough, where he graduated as M.B. and Ch.M. in 1871 and entered the army as surgeon on August 4th 1878, becoming lieutenant colonel after twenty years service and retiring on May 11th, 1904. He served in the South African war in 1901-2, taking part in operations in the Transvaal and in the Orange River Colony, and received the Queen's medal with three clasps. His two younger brothers also served in the R.A.M.C.—Colonels A.V. Lane and C.A. Lane.

Obituary

DIARMID NOËL PATON, B Sc, M D, LL D, F R S,
Late Regius Professor of Physiology in the University of
Glasgow

D NOËL PATON—whose death on Sunday, September 30th, at Stobo, Peeblesshire, was briefly announced in our last issue—had only recently intimated his desire to retire from the professorship of physiology in the University of Glasgow—in fact, the necessary appointments in consequence of his resignation have not yet been made. He was a born and indefatigable worker, and had always prayed that he might be taken away suddenly and after his power for work had gone. Since his official resignation some few weeks ago he had not been quite in his usual health, and on Sunday, during a walk to his favourite Tweed, where many a happy day had been spent casting the fly and no doubt meditating on the problems of life which he was so fond of probing, he passed suddenly away.

Diarmid Noel Paton was born in Edinburgh in March, 1859. He was the eldest son of Sir Joseph Noël Paton, the distinguished artist and Royal Scottish Academician, and nephew of Walter Hugh Paton, another well-known painter, so that there is little wonder that he inherited a distinctly artistic temperament. He received his early education at Edinburgh Academy, where, as Professor Cathcart has noted, he had as classmates "W. Hardman, afterwards professor of zoology at Liverpool, John Haldane, the Oxford physiologist and philosopher, and D'Arcy Thompson, the present occupant of the chair of zoology at St Andrews." It is said that it was at Edinburgh Academy where his bias towards science first declared itself, and one wonders what was the influence which led this galaxy of talent in this special direction. From the Academy Noël Paton passed to the University in his native town, and first graduated in science in 1880, when he was awarded the Baxter Scholarship for special distinction. In 1882 he received the degrees of M B, C M with first-class honours, a performance which was repeated in 1885, when he was awarded a gold medal for the thesis which he submitted for the degree of M D. After graduation he spent some time in post-graduate study in Vienna, returning again to Edinburgh to serve as house-physician, first in the Royal Infirmary, and later in the Royal Hospital for Sick Children. These latter experiences undoubtedly influenced his outlook and sympathies, for most of Paton's energies have been devoted to the study of eminently practical aspects of medicine, as his work on diabetes, rickets, and nutrition amply testifies. In 1884 he was offered and accepted a biological fellowship in the physiological department at Edinburgh University, under his old teacher, Professor Rutherford. In 1889 he was appointed

director of the research laboratory of the Royal College of Physicians of Edinburgh, and thus was able to devote his whole time to medical research and teaching. During this period he made many contributions to medical literature and carried on a most successful extramural class of physiology at the Surgeons' Hall, so that he was peculiarly equipped for the professorship of physiology in the University of Glasgow, to which the King appointed him in 1906. In 1914 his position in the scientific world was acknowledged by his election as a Fellow of the Royal Society, and in virtue of his gifts as an investigator he served as a member of the Medical Research Council from 1918 till 1923. In 1919 his Alma Mater, Edinburgh University, conferred on him the honorary degree of LL D.

PROFESSOR D NOËL PATON M D, F R S

It is as the Regius Professor of Physiology in the University of Glasgow that Noel Paton will be chiefly identified. This is most fitting, since he spent his most vigorous years in unrelenting work on her behalf and that of her students. Without doubt Paton was one of the most ideal professors in the medical faculty of the University of Glasgow within living memory, for he possessed in a marked degree that rare combination of qualities so essential for the head of a university department. One often hears of the professor who goes on delivering the same lectures year after year. Not so Paton, who was a firm believer in the doctrine that his chief duty as a teacher is to make the student an observer and a true student of nature. In order, therefore, that the student might commence on his study of medicine and surgery with a well-equipped mind so far as physiology is concerned, a most important attribute as the old name of his subject "Institutes of Medicine" signifies, Paton would not infrequently revise completely and rearrange his whole course of instruction. This meant a considerable amount of labour and

organization, as he always had a large department under his care, but this he considered well expended if his aim was fulfilled. This aspect of Noel Paton's work as a teacher cannot be too strongly emphasized.

But the teaching of the student in the elements of physiology was not Paton's only interest, important as this may be in giving to the youth a sane outlook, like all great teachers, he appreciated that his ignorance was greater than his knowledge, and all his life he was an energetic explorer into the unknown fields. Invariably he was working at some problem of life, and consequently has left his impress on many aspects of physiology and medicine. His work on urea, the physiology and pathology of the parathyroid glands, on respiration, his dietary studies of the labouring classes, and his investigation of the relationship between poverty, nutrition, and growth are all of the first importance, and will require serious consideration by all subsequent workers.

Paton was a true and an able researcher, he was always asking himself the why and the wherefore, he could not

deceive himself by a mere play of words, and he was never ashamed of admitting his ignorance. He might have theorised, but he frankly admitted that they were theories and merely signposts for directions of inquiry. He was also undoubtedly possessed of the rare faculty of imagination, which is not surprising when we recollect that both his father and uncle were distinguished artists.

As well as being a searcher after truth himself, he had the gift of inspiring others with the same ambition, and no man ever attracted a larger band of workers round him. His department was always open to anyone who needed facilities to work at a problem, and when once a man or woman gained entrance to a corner in his workshop Paton gave of his advice and help in no stinted fashion. His was the department to which all those eager to engage in comparative medicine and surgery turned. Not only was he an excellent director, but he was at the same time an ideal co-worker. He was a stimulating colleague; he always took a big share in the work of any investigation with which he was associated, and he gave and took criticism in the freest manner, so that at the end of the task one's admiration for his mental powers and regard for his genuineness were enhanced.

That Paton was a big and generous man there is no question. He had a great presence; he was tall, with regular, almost beautiful, features, and a kindly expression. He was as open as the day, in fact, his frankness and his loyalty to friends and his intolerance of dishonesty must often have brought trouble to himself. With the utmost truth it may be said that his is a memory which will remain as a great stimulus to a vast number of students and co-workers.

L F

[The photograph reproduced is by J Russell and Sons Ltd London.]

Dr JAMES THOMAS CURRIE LAING, who died in London on October 7th at the age of 57, received his medical education at Edinburgh, where he graduated M.B., C.M. in 1892. He was a member of the British Medical Association. We are indebted to Sir James Purves-Stewart for the following appreciation. The death of Dr J. T. C. Laing, or "Jimmy Laing," as he was affectionately called by his friends, colleagues, and patients, comes as a shock and an irreparable loss to all who knew him. Jimmy Laing was the finest type of Scot, a man of strikingly handsome physique and athletic build, tall, lean, and muscular, in his youth a fine boxer and throughout his life a keen sportsman. After graduating in Edinburgh in 1892 he was for a time house-surgeon to the late Professor Annandale. He then lived several adventurous years, first at the Klondike gold rush, when he held the post of assistant surgeon at the Good Samaritan Hospital, Dawson City, and later as a surgeon attached to the Canadian Scouts in the South African war. Subsequently he was induced to settle in London, where, by sheer force of personality, he speedily built up a practice of ever-increasing importance, not confined to London, but ultimately extending far beyond it. During the late war he did valuable work in London as physician to various hospitals for officers, and was mentioned in dispatches. For many years he was the popular secretary of the Edinburgh University Club of London, and later its vice-president. Up till about a year ago he sustained the burden of a large practice, apparently without effort. It then became evident to his friends that his physical strength was flagging. Despite a voyage to South Africa early in the present year, he found himself unable to continue his work in London, and accordingly spent the summer quietly in Scotland until a few days ago. He then returned to his home in London, where he rapidly succumbed to a pulmonary affection at the age of 57. Success never spoiled him, nor did he ever waver in loyalty to his friends. There was a singular charm about him which seemed automatically to attract the affection of his fellow men. His loss leaves a gap in the wide circle of his friends throughout the country which cannot be filled. If it be true of the good man that his works do live after him, then surely Jimmy Laing's memory will remain warm in the hearts of all who had the privilege of his friendship. Gay, debonair, humorous, modest, kindly, and wise, every-

one who knew him will agree that he possessed all these qualities. He leaves behind him a widow and youthful daughter and son, to whom the deep sympathy of his friends will be extended.

We regret to announce the death, at the age of 73, of Professor HOLGER RASMUS LILJEN MÖND, who was a pioneer of otology and laryngology in Denmark. He was the author of works on congenital deafness and deaf-mutism, and of a small textbook on diseases of the upper respiratory tract. An English translation of his work on deaf-mutism appeared in 1894. He had many friends in England, and his widow is the daughter of Mr S. Nash, formerly Danish consul at Cardiff.

The following well-known foreign medical men have died recently: Dr PROKOP FREIHERR VON ROKITSANSKY, professor of medical pathology and therapeutics at Innsbruck; Dr GUSTAV VON SCHLEICH, professor of ophthalmology at Tübingen; and Professor H. VON BARCKLEBEN, a Berlin gynaecologist, aged 54.

Universities and Colleges

UNIVERSITY OF CAMBRIDGE

THE outgoing Vice-Chancellor, the Rev G. A. Weekes in the course of his valedictory address in the Senate House on October 1st referred to the recent offer by the International Education Board of the Rockefeller Foundation to contribute £250,000 to the University Library Building Fund and explained that this munificent offer formed part of a larger proposal to provide for new and much needed developments in the physical and biological studies of the University. The offer in its entirety amounted to a gift of £700,000, on condition that the University should raise the balance of the sum required for the completion of the whole scheme. The offer had been considered, with approval by the Council, the General Board, and the Financial Board but had not as yet been laid before the University. Mr Weekes referred also to the loss sustained by the University through the death of Mr G. E. Wherry, consulting surgeon to Addenbrooke's Hospital, and for many years university lecturer in surgery. The building in Tennis Court Road which has been provided for the departments of pathology and animal pathology by a grant from the trustees of the Rockefeller Foundation and by the Gates Bequest is now in occupation and will be ready for the formal opening ceremony next term.

UNIVERSITY OF LONDON

At the September matriculation there were 100 successful candidates in the first division and 373 in the second division, 27 others took the supplementary certificate in Latin.

UNIVERSITY OF LEEDS

ROYAL COLLEGE OF SURGEONS OF ENGLAND

THE annual meeting of Fellows and Members will be held at the College, Lincoln's Inn Fields W.C. on Thursday, November 15th, at 3 p.m.

Medical News.

THE fourteenth annual conference of the National Association for the Prevention of Tuberculosis will be held in the Great Hall of the British Medical Association House, Tavistock Square, W.C.1, on October 15th and 16th. Sir Arthur Stanley will formally open the conference. The first day's discussion will be on the occurrence of tuberculosis among primitive people and the speakers will include Dr. R. O. Ferguson, Director of Medical Services of the Saskatchewan Anti-Tuberculosis League, Dr. J. J. Vassal, ex-Director of Health for French Equatorial Africa, and Professor S. Lyle Cummins. On the second day the subject for discussion will be the principles underlying a national anti-tuberculosis scheme, and the speakers will include Sir Robert Philip, Dr. Howard Holbrook, medical director of the Mountain Sanatorium, Hamilton, Canada, and Dr. G. Lissant Cox, tuberculosis officer for Lancashire.

A DINNER of the combined Yorkshire Associations of Scottish Graduates will be held at the Queen's Hotel, Leeds, on Friday, October 19th, at 7 p.m. The guests of the evening will be the three parliamentary representatives of the Scottish Universities, Sir George A. Berry, M.B., LL.D., Mr. John Buchan, LL.D., and Mr. J. M. Cowan, M.A. The chair will be taken by Dr. J. B. Baillie, Vice-Chancellor of Leeds University. All graduates of these universities resident in Yorkshire, whether members of the various associations or not, are invited to attend and to bring guests (including ladies) if they so wish. Tickets and any further information may be obtained from the honorary secretary of the combined dinner, Dr. William MacAdam, 40, Park Square, Leeds.

THE St. Thomas's Hospital annual old students' dinner will be held on Friday, October 26th, at 8 o'clock, at St. Thomas's House, Lambeth Palace Road, S.E. The chair will be taken by Mr. L. F. White, F.R.C.S.

At the annual festival service of the Guild of St. Luke in Westminster Abbey on Sunday, October 21st, at 6.30 p.m., the preacher will be the Rev. Canon C. S. Woodward. No tickets for admission are required, and medical practitioners are invited to attend.

THE Long Fox Memorial Lecture will be delivered by Dr. J. Odory Sykes in the Physiological Theatre of the University of Bristol on Friday, October 30th, at 8.30 p.m., the subject is the relation of erythema nodosum to tuberculosis and other diseases.

A MEETING of the Tuberculosis Association will be held at the house of the Royal Society of Medicine, 1, Wimpole Street, W.1 on Wednesday, October 17th, at 5.30 p.m., when Professor K. H. Plimmer will read a paper on recent work of vitamins. At 8 p.m. there will be a discussion on artificial pneumothorax treatment from different aspects.

THE first meeting of the new session of the West Kent Medical-Chirurgical Society will be held at the Miller General Hospital, Greenwich, to-day (Friday, October 12th), at 8.45 p.m. After the routine business a series of clinical cases will be shown.

As already announced, the second International conference on light and heat and medicine and surgery will be held in the University of London buildings at South Kensington from October 29th to November 1st. Sir Henry Ganvalm will discuss light therapy in relation to surgical tuberculosis, Dr. M. Weintraub its use in pulmonary tuberculosis, and Dr. W. J. O'Donovan its application in skin diseases. Dr. W. Kerr Russell will speak on apparatus for the production of ultra violet rays for medical purposes and Dr. C. B. Heald the development of new electrotherapeutic apparatus. Several speakers from foreign countries will take part in the conference. Dr. Franz Nagelschmidt (Berlin) will describe a new method of applying heat by diathermy and will open a discussion on ion treatment, Dr. W. Flakamp (Erlangen) will discuss light and heat in gynaecology, Dr. A. J. Cemach (Vienna) will give an address on ultra violet therapy in otorhino-laryngology, and Dr. M. J. Dorcas (Cleveland, U.S.A.) will read a paper on the distribution of energy from various types of arcs. An exhibition to be held in connexion with the conference will be opened on October 29th at 2.30 p.m. by Sir John Snell, chairman of the Electricity Commissioners, with Dr. I. E. Fremautle, M.P., in the chair.

The British Institute of Philosophical Studies has arranged for two courses of lectures during the forthcoming Michaelmas term: (1) Four great philosophers and the modern outlook, by Professor L. J. Russell, (2) Contemporary philosophy, by the director of studies, Mr. Sydney Hooper. A syllabus can be had on application to the temporary offices of the Institute, 88, Abingway, W.C.2.

A COURSE of nine lectures on "The indebtedness of industry to pure science," under the auspices of the Faculty of Science, will be given at King's College, Strand, W.C., during the Michaelmas term on Wednesdays at 5.30 p.m., beginning on October 17th, when an introductory address will be delivered by Sir Oliver Lodge. The succeeding lectures will be given by members of the staff, among them will be an address, on November 7th, by Dr. F. A. P. Aveling on "The human factor," while a week later Professor R. J. S. McDowall will speak on "Physiology and national efficiency." Admission is free, without tickets.

AMONG the public lectures to be given at University College, Gower Street, W.C.1, during the winter months of the year is a course of three by Dr. John Owens on "Smoke pollution of the air and public health." The first lecture will be given on Friday, November 2nd, at 5.30 p.m., with Sir Napier Shaw in the chair, and the others on Friday, November 9th, and Wednesday, November 14th, at the same hour.

THE Fellowship of Medicine and Post-Graduate Medical Association announce that the opening lecture of its new series will be given by Mr. O. Max Page, on Monday, October 15th, in the lecture hall of the Medical Society of London, 11, Chandos Street, Cavendish Square, W., the title of the lecture will be "Some points in the treatment of fractures." On Wednesday, October 17th, clinical demonstrations will be given by Mr. Jefferson Fawcett, at the Golden Square Throat Hospital, at 3 p.m., and by Dr. G. B. Dowling at the St. John's Hospital for Diseases of the Skin, at 4 p.m., and at the same hour will be the second demonstration of the series undertaken by Dr. S. H. Dawkes, at the Wellcome Museum of Medical Science, 35, Gordon Square, W.C.1, his subject being "The transmission of harmful diseases." The above lectures and demonstrations are open to the medical profession without fee. A fortnight's morning course by the honorary staff of the Hospital for Sick Children will begin on October 15th, and Professor Lennox Mollroy will give four lecture demonstrations on ante-natal treatment at the Royal Free Hospital beginning on Friday, October 26th. There will be a general practitioners' course at the Hampstead General Hospital from October 29th to November 10th, from 4.30 to 6 p.m. daily. Special courses will be held during November, in medicine, surgery, and gynaecology at the Royal Waterloo Hospital for Children and Women, in neurology at the West End Hospital for Nervous Diseases, in ophthalmology at the Royal Westminster Ophthalmic Hospital, in proctology at St. Mark's Hospital, in urology at St. Peter's Hospital, and in venereal diseases at the London Lock Hospital. Copies of all syllabuses and other information may be obtained from the Secretary of the Fellowship, 1, Wimpole Street, London, W.1.

THE Marquis of Reading presided for the first time as Chairman of the Grand Council of the British Empire Cancer Campaign at its quarterly meeting held on October 8th. The proceedings opened with a vote of condolence on the death of Dr. Robert Knox, one of the founders of the Campaign and a member of the Grand Council. The following grants were approved on the recommendations of the appropriate committees of the Campaign—£500 as a supplementary grant towards the maintenance of cancer research work at the Middlesex Hospital, £500 to the Cancer Research Committee of the London Association of Medical Women's Federation for the salary of its research officer for one year, £200 to Mr. Nevill Willmer of Manchester University for the continuation of his research work, £50 to the Clinical Research Committee of Guy's Hospital towards the cost of an investigation on organic compounds of lead with a view to their therapeutic use, and a sum of £1,500, spread over a period of three years, to the Middlesex Hospital for the salary of an assistant histologist. A donation of £3,000 was announced from an anonymous donor, in addition to a previous sum of £10,000 from the same benefactor. A letter was received from the newly formed International Cancer Committee, which has been set up to deal with the organization of International Conferences on Cancer in future years, and the Grand Council nominated Mr. W. Sampson Handley, Dr. R. G. Cantl, and Professor Archibald Leitch as its representatives on this International Committee. Approval was given to the proposed scheme for setting up a special committee to investigate and report upon the data and results that had become available through the International Conference on Cancer held in July. The Grand Council elected Sir Thomas Horler as its representative on the Scientific Advisory Committee, nominated jointly by the Royal Society, the Medical Research Council of the Privy Council, and the Campaign.

THE post-graduate courses of instruction at the National Hospital, Queen's Square, Bloomsbury, recommenced on October 8th and will be continued on succeeding Mondays, Tuesdays, Thursdays, and Fridays terminating on November 30th. The course consists of out-patient clinics, clinical lectures and demonstrations, lectures on the pathology of

the nervous system, and on the anatomy and physiology of the nervous system, together with clinical demonstrations on methods of examination. Any part of the course may be taken separately. The fee for the course, including pathology demonstrations, is £5 5s., for those holding perpetual tickets £3 3s., and clinical clerks £4 4s.

THE Central Midwives Board for England and Wales, at a meeting on October 4th, had under consideration a communication from the Association of Municipal Corporations enclosing a letter to the Ministry of Health in regard to the conduct of cases before the Board. In this letter the Association urged the Ministry to give effect to a resolution adopted by the City Council of Canterbury expressing the opinion that the conduct of cases before the Central Midwives Board should be left in the hands of local authorities, that the attendance of witnesses should be made compulsory, and that all evidence in such cases should be given on oath. The Board approved Nether Edge Hospital, Sheffield, as a training school, subject to certain conditions, and also granted approval *pro tem*, as a lecturer, to Dr. W. B. Wishart.

THE fifth international congress for the treatment of industrial accidents and industrial hygiene, which was held at Budapest during the first week in September, was opened by Professor Kaufmann of Zürich, who delivered a lecture on the differentiation of trauma and disease. Sir Thomas Oliver read a paper on the influence of industrial poisons on the different organs, with special reference to lead, arsenic, and mercury. Among the other subjects considered were the physiological response to the vapours of methyl and ethyl salts, the nervous sequelae of accidents, pulmonary asbestosis, and the medico-legal aspects of occupational disease. The congress was visited by a large number of delegates from many countries.

AS on several previous occasions the Société Médical du Littoral Méditerranéen has arranged an international medical tour of the Côte d'Azur to take place just after Christmas. Assembling at Marseilles on the evening of December 26th, the party will spend two days in visiting that neighbourhood and then, proceeding afterwards to Hyeres, Cannes, Juan les Pins, Antibes, Nice, Monaco, and other places, where scientific demonstrations, therapeutic discussions, etc., will be arranged. Visits will be made to various centres of interest, including Dr. Veronoff's laboratory and the oceanographic museum at Monaco. At the conclusion of the tour, on January 5th, members of the party may proceed on an excursion to the Alps or on an excursion to Corsica, or may spend some days at Nice. Particulars may be obtained from Dr. M. Fanro, 24 rue Verdil, Nice.

Letters, Notes, and Answers.

All communications in regard to editorial business should be addressed to **The EDITOR, British Medical Journal, British Medical Association House, Tavistock Square, W.C.1**

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the British Medical Journal, alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names, not necessarily for publication.

Authors desiring REPRINTS of their articles published in the British Medical Journal must communicate with the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W.C.1, on receipt of proofs.

All communications with reference to ADVERTISEMENTS as well as orders for copies of the JOURNAL, should be addressed to the Financial Secretary and Business Manager.

The TELEPHONE NUMBERS of the British Medical Association and the British Medical Journal are *ALSEUM 9561 9562 9563* and *9564* (internal exchange, four lines).

The TELEGRAPHIC ADDRESSES are EDITOR of the British Medical Journal, *Anthology Westcott, London*.

FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements etc.) *Articulate Westcott London*.

MEDICAL SECRETARY *Medicera Westcott London*.

The address of the Irish Office of the British Medical Association is 16 South Frederick Street, Dublin (telegrams *Bacillus Dublin* telephone 62550 Dublin), and of the Scottish Office 7 Drumshugh Gardens Edinburgh (telegrams *Associate, Edinburgh* telephone 24361 Edinburgh).

QUERIES AND ANSWERS

TREATMENT OF POST NASAL CATARRH

"A. X." asks for advice with regard to the treatment of an otherwise healthy man aged about 60 who has suffered from post-nasal catarrh for two years. No benefit has resulted from a course of anticholinergic vaccines or the use of an atomizer. There is a copious viscid and sometimes purulent secretion from the pharynx and back of the nose, with occasional dribbling from the nostrils.

INCOME TAX

Fees Paid by Practitioners

"W. J. M." has been requested by the income tax authorities to supply the names and addresses of medical men to whom he has paid fees of £10 and upwards during 1927-28 for assistance at surgical operations.

The relative statutory provision in Section 105 of the Income Tax Act, 1918, under which an "employer" can be called upon to give such particulars in respect of persons "employed" by him. The objection which, as it seems to us, our correspondent may very well be entitled to make is that the medical men in question are not in his employment, but both are in the position of jointly earning fees for work done for a patient. The question raises a somewhat difficult point of general law, but the normal case would, we think, fall outside the statutory rule.

LETTERS NOTES ETC.

MR. FRANK ROMER (London, W.) asks our help in regaining touch with the secretary of a medical society with whom he has been in correspondence about the reading of a paper. His dilemma arises from the accidental destruction of letters and memoranda during a holiday.

MALIGANCY AND THE ENZYME

DR. W. C. MINCHIN (Sheerness-on-Sea) in reply to Lieut. Colonel V. N. Whitmore's inquiry (September 15th, p. 514) writes to suggest a simple explanation. While Murphy and his fellow workers are satisfied that cancer is due to ferment Gye has shown by filtering cancerous material that neither the filtrate nor the material left on the filter was active though when they were again mixed, activity was restored. Dr. Minchin suggests that these results are more similar than might appear at first sight and he quotes Chaston Chapman's book on brewing, in which, after a review of some of Pasteur's work upon yeasts, reference is made to Buchner's discovery in 1897 that the liquid contents of the yeast cell when added to a fermentable liquid, could excite fermentation in the absence of any cells. Buchner concluded that fermentation resulted from the activity of an enzyme secreted by the yeast cell to which he gave the name "zymase." Harden found by passing yeast juice through a Chamberland filter impregnated with gelatin that neither the filtrate nor the residue could bring about fermentation separately, though by mixing the two portions activity was restored. Harden recognized, thus, that the enzyme which remained on the filter required contact with the filtrate, the active constituent of which he designated the coenzyme, the true chemical nature of this is still undetermined. Dr. Minchin adds: "I have shown in my book on the tubercle virus published by Messrs. Baillière, Tindall and Cox that yeasts are always to be found in cancerous and tuberculous material even in the filtrates and diseased tissue. A direct photomicrograph in my possession of a section of a cancer growth of the tongue plainly shows budding yeasts when stained by the Ziehl method."

EXAMINATION OF THE FAECES FOR TUBERCLE BACILLI

DR. C. D. GALLAGHER (assistant medical officer, Levensden Mental Hospital) has contributed to the annual report of the Metropolitan Asylums Board for 1927-28 an account of an investigation into the examination of the faeces for tubercle bacilli in the case of mental patients. He concludes that the direct smear examination of faeces is worthy of employment in all cases. In the event of a negative result being obtained the concentration method with litmus may be tried. In some cases of febrile symptoms occurring in low grade tubercles such investigation of the faeces has been found to be helpful in clearing up the diagnosis since these patients cannot as a rule, be taught to expectorate their sputum, which they swallow.

FALLING BIRTH RATE AND CRUMBLING EMPIRES

DR. GEORGE JONES (Downe, Kent) writes Dr. Stephenson (October 6th, p. 634) refers to the fall of the West Roman Empire under Honorius in 410. He thinks it was due to the increase of the parasite class which demanded *panem et circenses* both free and at the expense of the provincials. Now the East Roman Empire survived for another thousand years. Constantinople was no better than Rome. What does seem to have been the immediate cause of the fall of Rome was the murder of Stilicho at the instigation of the cowardly Emperor Honorius who skulked in the marshes at Ravenna while the barbarians entered Rome. We ought to remember that under Justinian Africa and Italy were largely free from barbarians, but the civilization of the West Empire was never recovered. There must have been other causes in operation when they were. Gibbon has hinted only too clearly to those who read between his sonorous lines. The utter misery of the West under the barbarians may be gathered from Salvian's *De Gubernatione Dei* or from Cardinal Newman's University Studies. Not even Russia has gone through worse experiences.

VACANCIES

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals will be found at pages 48, 49, 50, 51, 54, and 55 of our advertisement columns, and advertisements as to partnerships, assistantships, and locum tenencies at pages 52 and 53.

A short summary of vacant posts notified in the advertisement columns appears in the Supplement at page 163.

The Harveian Oration

ON

CARDIO-VASCULAR DISEASES SINCE
HARVEY'S DISCOVERYDELIVERED BEFORE THE ROYAL COLLEGE OF PHYSICIANS OF
LONDON, OCTOBER 18TH, 1928,

BY

SIR HUMPHRY ROLLESTON, BART, K C B, M D,
HON. D.Sc. D.C.L., LL.D.FELLOW AND SOMETIME PRESIDENT OF THE ROYAL COLLEGE OF PHYSICIANS
OF LONDON PHYSICIAN IN ORDINARY TO THE KING, REGIUS
PROFESSOR OF PHYSIC, CAMBRIDGE

INTRODUCTION

THE President's command to deliver the 272nd Harveian Oration in the tercentenary year of the publication of the *Exercitatio Anatomica de Motu Cordis et Sanguinis in Animalibus* is an honour to be prized with humble gratitude, but with a due sense of its heavy responsibility, by any man, especially by one whose father obeyed the call to this high duty fifty-five years ago.

The tercentenary of the publication of Harvey's immortal discovery was appropriately and splendidly commemorated by the celebrations organized by this College. In no way could its significance have been more suitably and graphically shown than by the remarkable cinematograph films of Harvey's original physiological experiments as repeated by Sir Thomas Lewis and Dr H. H. Dale, Fellows of the College, who have been eminent in obedience to Harvey's exhortation "to search and study out the secrets of nature by way of experiment." Further, the historical aspect of the tercentenary has been permanently assured by the publication by the College of a facsimile of the first edition of the *De Motu Cordis*, and by the appearance of two other Harveian books, a reproduction of the first English translation in 1653 of the *De Motu Cordis* (Nonesuch Press), and *A Bibliography of the Writings of William Harvey, M.D.* (Cambridge University Press), both due to the pious devotion of a licentiate of the College, Mr Geoffrey Kovnes.

John Freind, the elegant scholar and eminent physician, when commenting on the history of the circulation, wrote in 1725:
